1 Zusammenfassung und wissenschaftlicher Erkenntnisgewinn

Im Jahr 1975 konnten die Wissenschaftler Köhler und Milstein erfolgreich B-Lymphozyten aus immunisierten Mäusen mit Myelomzellen fusionieren und mittels dieses, als Hybridoma Technologie bezeichneten Verfahrens, Zellen erzeugen die Vorteile beider Vorgängerkzellen vereinen. Diese immortalisierten Hybridomazellen sind sowohl kultivierbar, als auch in der Lage Antigen spezifische Antikörper zu sezernieren. Ihre bahnbrechende Erfindung für die Herstellung von Antikörpern wurde 1984 mit dem Nobelpreis honoriert.

Allerdings stellt die Hybridoma Technologie einen langwierigen Prozess mit geringer Effizienz dar. Zusätzlich ergibt sich durch die murine Herkunft der Antikörper eine potenzielle Immungenitätsproblematik bei Applikation im Menschen.

Aus diesen Gründen wurden in den letzten Jahrzehnten verschiedene Technologien zur Überwindung dieser Limitationen entwickelt. Sie umfassen dabei die Nutzung von humanen naiven, semi- oder komplett synthetischen Antikörperdiversitäten (zur Vermeidung der Immungenitätsproblematik) in Verbindung mit zellulären oder nicht-zellulären in vitro Selektionssystemen zur Präsentation und Isolation von Antikörpern, wie z.B. das Phagen- oder Hefe-Display. Durch die Entwicklung dieser Methoden konnten große Repertoires bezüglich vorgegebener Eigenschaften durchmustert und spezifische Moleküle isoliert werden, was den heutigen, erfolgreichen Einsatz von monoklonalen Antikörpern in biotechnologischen und medizinischen Anwendungen unterstützte. Trotz aller Verbesserungen im Antikörperfindungsprozess stellt die Generierung der initialen Display-Bibliotheken immer noch einen aufwendigen und anspruchsvollen Prozess dar. Dieser ist oft mehrstufig und umfasst am Beispiel des Hefe-Displays verschiedene Klonierungsschritte, die Erstellung von getrennten Bibliotheken für schwere und leichte Ketten, sowie letztlich deren Paarung durch *Mating*.

Dieser Ablauf kann durch die Anwendung von *Golden Gate Cloning* (GGC) vereinfacht werden und in nur einer Reaktion erfolgen. Die Klonierungsreaktion im GGC beruht dabei auf der Nutzung von Typ II Restriktionsenzymen. Diese Enzyme schneiden DNA in einer definierten Distanz außerhalb ihrer Erkennungssequenzen und ermöglichen dadurch die Inkorporation von Überhängen mit gewünschter Signatur. Typ II Restriktionsenzyme erlauben somit einen gerichteten, einstufigen Klonierungsprozess, bei dem die Erkennungssequenzen während der Reaktion entfernt und das Reaktionsgleichgewicht auf die Seite des spezifischen Klonierungsproduktes verschoben wird.

In der vorliegenden Arbeit konnte anhand von drei unterschiedlichen Selektionskampagnen die Anwendbarkeit von GGC für die Bibliotheks-Generierung im Hefen- und Phagen-Display demonstriert werden.

Dabei wurden spezifische Fab Antikörper gegen CEACAM6, EGFR und hCG aus Immunrepertoiren von transgenen Ratten und Wildtyp Hühnern (Hefe-Display), sowie EGFR spezifische scFv und VHH Antikörper aus Immunrepertoiren von Hühnern und Kameliden (Phagen-Display) isoliert. GGC konnte dabei im

Vergleich zur klassischen Generierung von Antikörper-Bibliotheken bezüglich Verteilungen der Genrepertoires, der allgemeinen Bibliotheks-Größen, sowie biophysikalischer Charakteristika der isolierten Antikörper validiert werden. Der entwickelte, einstufige GGC Prozess ist in der Lage Antikörper Bibliotheken basierend auf kombinatorischen schweren und leichten Ketten Diversitäten mit gleicher Qualität gegenüber der traditionellen Methode zu generieren. Zusätzlich bietet er den Vorteil einer schnelleren und weniger aufwendigen Methodik, da er die multiplen Schritte des traditionellen Ansatzes parallelisiert.

Neben klassischen monoklonalen Antikörpern und Antikörperfragmenten bieten neue Antikörperformate Ansätze zur therapeutischen Anwendung. Dazu zählen Moleküle wie bispezifische Antikörper (bsAbs) und Immunoliganden, sowie andere Antikörperfragmente und -derivate, z.B. kamelide Einzeldomänenantikörper-Fc Fusionen.

Bei der Herstellung von IgG-basierten bispezifischen Antikörpern, bestehend aus zwei unterschiedlichen schweren und zwei unterschiedlichen leichten Ketten, müssen theoretisch vier unterschiedlichen Plasmide für deren Expression in der Zellkultur eingesetzt werden, was zu einer statistischen Ausbeute von lediglich 12.5 % des gewünscht assembliertem Proteins führt. Eine Möglichkeit die Heterogenität bei der Expression von mehreren gleichgearteten Polypeptidketten zu umgehen, ist die Nutzung der Strand-Exchange Engineered Domain (SEED) Technologie. Durch die Einfügung alternierender IgA und IgG β -Faltblatt Strukturen in den CH3 Domänen, entstehen anti-parallele Immunglobulinstrukturen, die eine Heterodimerisierung der schweren Ketten begünstigen. Zur Vermeidung von Homodimerisierung der schweren Ketten wurden neben SEED noch andere Technologien wie „knob-into-holes“, controlled Fab arm exchange oder gezielte Aminosäure-Austausche zur Einführung von konträren elektrostatischen Ladungen in den beiden schweren Ketten entwickelt.

Um darüber hinaus eine leichte Ketten-Fehlpaarung der Antikörper zu verhindern, wurden ebenfalls diverse Technologien entwickelt, wie z.B. CrossMab oder die Nutzung einer Common Light Chain. Eine weitere Möglichkeit hierfür besteht zusätzlich in der Verwendung von kameliden VHH Domänen. Diese nutzen nicht die für den kanonischen Antikörper notwendige leichte Kette, sondern stellen eine spezifische Antigen-Bindung ausschließlich über die variable Domäne der schweren Kette her.

In diesem Kontext war ein Ziel der vorliegenden Arbeit die Kombination der SEED Technologie mit einem 2013 von Baty und Kollegen konzeptionell beschriebenen Fab ähnlichen bispezifischen VHH Antikörper. Dies ermöglichte die Generierung einer neuartigen bi- und trispezifischen, IgG-ähnlichen VHH basierten Antikörperplattform mit damit verbundenen variablen Valenzen im Rahmen dieser Promotion. Die Ergebnisse der Charakterisierung dieses Antikörperformats bezüglich ihrer biophysikalischen und biochemischen Eigenschaften, wie z.B. spezifischem, NK-Zell vermitteltem ADCC, belegten die Vielseitigkeit dieser generischen Plattform zur Expression voll funktioneller mono-, bi und trispezifischer Antikörper mit unterschiedlichen Valenzen als „plug-and-play“ Anwendung.

Darüber hinaus ist der Einsatz von bispezifischen Molekülen für die gerichtete NK-Zell Rekrutierung in heutiger Zeit von großem Interesse. Die spezifische NK-Zell Rekrutierung zu tumorösen oder infizierten

Zellen ermöglicht eine spezifische Zytolyse der Zielzellen und die gleichzeitige Immunmodulation durch eine NK-Zell vermittelte Zytokin-Freisetzung.

Eine Möglichkeit, um die Rekrutierung von NK-Zellen zu adressieren, bieten die von diesen Zellen umfassend exprimierte natürlichen Cytotoxischen Rezeptoren (NCRs). In dieser Arbeit konnte mittels Hefe-Display die bindungsrelevante N-terminale IgV-ähnliche Domäne des natürlichen Liganden B7-H6 für den NCR Rezeptor NKp30 affinitätsmaturiert werden. Mittels *Fluorescence Activated Cell Sorting* (FACS) basierter Selektion wurden B7-H6 Varianten mit signifikant erhöhter Affinität zu NKp30 erhalten. Auch zeigten diese Varianten bei der Anwendung im Format bispezifischer Immunoliganden signifikant gesteigerte NK-Zell vermittelte Zytotoxizitäten und Zytokin-Freisetzungen gegenüber dem parentalen B7-H6 Molekül.

Diese Erkenntnisse belegen die zu Grunde liegende Hypothese, dass eine gesteigerte Affinität von B7-H6 zu NKp30 in einer erhöhten NK-Zell basierten Tumorzell-Zytolyse und einer gesteigerten NK-Zell vermittelten Sekretion von proinflammatorischen Zytokinen resultiert. Eine Affinitätssteigerung von natürlichen Liganden aktivierender NK-Rezeptoren könnte somit zur Entwicklung potenzieller Immuntherapeutika zur Behandlung von Patienten mit unterschiedlichen Krebserkrankungen verwendet werden.

2 Scientific novelty and overview

In 1975, scientists Köhler and Milstein successfully fused B-lymphocytes from immunized mice with myeloma cells and, through this procedure entitled hybridoma technology, were able to combine the advantages of both precursor cells. These immortalized cells are culturable and able to secrete antigen-specific antibodies. The scientists' invention, revolutionary for the production of monoclonal antibodies, was awarded with a Nobel Prize in 1984.

It became apparent, however, that the hybridoma technology is a lengthy process with low efficiency. In addition, the murine origin of the antibodies causes a potential problem with immunogenicity when applied to humans.

Several new technologies have been developed in the last decades in order to overcome these limitations. These technologies include the use of human naïve, semi-synthetic or synthetic antibody diversities (to avoid the immunogenicity issue) in combination with cellular or non-cellular in vitro selection systems for the presentation and isolation of antibodies, such as Phage or Yeast Display. By the invention of these methods, large repertoires could be examined for predefined characteristics, thus enabling the isolation of specific molecules, which advanced today's successful use of monoclonal antibodies in biotechnological and medical applications. Despite all improvements in the finding process of antibodies, the generation of initial display libraries is still complex and laborious. It is often a multistage process which, as with Yeast Display, encompasses multiple cloning steps, the generation of separated libraries for heavy and light chains as well as, ultimately, their mating. This process can be simplified and condensed to only one reaction through the application of *Golden Gate Cloning* (GGC). The cloning reaction within GGC is based on the use of Type II restriction enzymes, which digest DNA in a defined distance from their recognition sequences and, thereby, allow for the incorporation of overhangs with requested signatures. Type II restriction enzymes enable a targeted, single-stage cloning process in which all recognition sequences are removed during the reaction, thereby causing an equilibrium shift towards the specific cloning product.

As part of this work, the feasibility of GGC for the generation of Yeast and Phage Display libraries could be demonstrated for three different selection campaigns. Specific Fab antibodies against CEACAM6, EGFR and hCG were isolated from the immune repertoires of transgenic rats and wild type chickens (Yeast Display), and EGFR-specific scFv and VHH antibodies were isolated from the immune repertoires of chickens and camelids (Phage Display). In comparison to the traditional generation of antibody libraries, GGC could be validated with regards to gene repertoire distribution, the overall size of libraries as well as to the biophysical characteristics of isolated antibodies. The developed single-stage GGC process is able to generate antibody libraries based on combinatorial heavy and light chain diversities with the same quality as the traditional method. In addition, the process is a faster and less laborious method, which parallels the multiple steps of the original approach.

Besides classical monoclonal antibodies and antibody fragments, new antibody formats can broaden the therapeutic space of new biological entities. Among these are molecules such as bispecific antibodies (bsAbs) and immunoligands, as well as other antibody fragments and derivatives - such as camelid single domain antibody Fc-fusions.

In theory, four different plasmids have to be used during the expression of IgG-based bispecific antibodies in cell culture, as they consist of two different heavy chains and two different light chains. This would lead to a statistical yield of only 12.5 % of the desired assembled protein. The Strand Exchange Engineered Domain (SEED) technology is one possibility to avoid heterogeneity during the expression of several similar polypeptide chains. Through the introduction of alternating IgA and IgG β -sheet structures in the CH3 domains, antiparallel immunoglobulin structures occur, which promote a heterodimerization of the heavy chains. In order to avoid heavy chain homodimerization, additional technologies, such as "knob-into-holes", controlled Fab arm exchange or targeted amino acid exchanges used to introduce contrary electrostatic charges into both heavy chains have been developed.

Moreover, mispairing of antibodies light chains can be prevented by technologies such as CrossMab or the use of a Common Light Chain. Another possibility is the utilization of camelid VHH domains. VHHs, compared to canonical antibodies, provide specific antigen binding exclusively via the variable domain of the heavy chain.

In this context, it was one of the goals of the present work to combine the SEED Technology with a bispecific Fab-like VHH antibody which was conceptually described by Baty and coworkers in 2013. This combination enabled the generation of a novel bi- and trispecific, IgG-like VHH-based antibody platform with related variable valences.

The results of the characterization of this antibody format with regards to its biophysical and biochemical characteristics - such as the specific NK cell-mediated ADCC - verify the versatility of the generic platform in expressing fully functional mono-, bi- and trispecific antibodies with different valences as a "plug and play" application.

Furthermore, the use of bispecific molecules for a targeted NK cell recruitment is of substantial interest nowadays. The specific NK cell recruitment towards tumorous or infected cells enables a specific cytolysis of target cells and a simultaneous immune modulation through NK cell-mediated cytokine release.

One possibility to address the recruitment of NK cells are the Natural Cytotoxicity Receptors (NCRs), comprehensively expressed by NK cells. For this work, and through the use of Yeast Display, the *N*-terminal IgV-like domain of B7-H6 (natural ligand of NKp30), which is relevant for receptor binding, could be affinity matured. Via *Fluorescence Activated Cell Sorting* (FACS)-based selection, B7-H6 variants with significantly increased affinity to NKp30 were achieved. Additionally, these variants showed significantly increased NK cell mediated cytotoxicities and cytokine release when used in the format of bispecific immunoligands, compared to the parental B7-H6 molecule.

These results verify the underlying hypothesis that an increased affinity of B7-H6 to NKp30 results in an increased NK cell-based tumor cell cytolysis as well as in increased NK cell-mediated secretion of

proinflammatory cytokines. An increased affinity of activating NK cell receptors natural ligands could, therefore, be used in the development of potential immunotherapies for the treatment of patients with various cancerous diseases.

3 Introduction

3.1 Antibodies

Lymphocytes are the prime mediators of the adaptive immune system, eliminating invading pathogens. They recognize the foreign structures by their specific antigen receptors. During lymphocyte maturation, B cells and T cells undergo a unique rearrangement of germline encoded, antigen independent gene segments, finally forming a specific B cell (BCR) or T cell (TCR) receptor, which then allows recognition of foreign structures. This process involves different stages of maturation and comprises several steps of genetic diversification, explained in more detail in the following sections.

Antibodies can be termed as “final product” of matured and activated plasma B cells and represent the humoral immune response of the adaptive immune system in vertebrates, recognizing and binding to structures of foreign proteins.

The humoral immune response was first described by van Behring and Kitasato in 1890, who discovered an antitoxic blood serum component in immunized rodents which could neutralize diphtheria toxin [1]. In the 1930s, this discovery was refined by other scientists like Heidelberger and Kendall, however, especially by Tiselius and Kabat in 1939 [2], [3]. They were able to separate serum via electrophoresis into alpha (α), beta (β) and gamma (γ)-globulin fractions and showed “that the antibody function migrated with the γ -globulin fraction only”, paving the way for the present terminology immunoglobulin (*Ig*) and IgG. The γ -globulin portion was then fractionated by sizing columns into heavy fraction, containing IgM, and regular fraction, comprising IgA, IgD, IgE and IgG.

3.1.1 Structure of antibodies

Antibodies are large molecules secreted by matured, activated plasma B cells, forming in monomeric state a Y-shaped molecule consisting of two similar homodimerized heavy chains and two identical light chains (H_2L_2) covalently connected via disulfide bonds [4]. Each chain contains variable and constant regions, defining the antigen-binding specificity and the immune-mediated activities, referred to as effector functions. These two moieties, both consisting of Ig-like β -pleated sheets, can be further defined as Fab (antigen binding fragment), which is responsible for the antigen interaction, and Fc (crystallizable fragment), responsible for the effector functions. The largely conserved constant heavy chain regions (CH) are responsible for the antibodies effector functions and define the molecules isotype IgA, IgD, IgM, IgG or IgE. IgG and IgA can be further divided into subclasses IgA1 and IgA2 as well as IgG1-4. Each of these isotypes facilitate different immune-mediation mechanisms like antibody localization, polymerization or the interaction of the antibody with different immune cells by various Fc receptors [5]. In contrast to CHs, constant light chain domains (CL) which are divided into kappa (κ) and lambda (λ) domains increase the

diversification of the antibody repertoire and elevate the ratio of functional proteins during the B cell maturation rather than participate in immune-mediation activities. The Fab fragment consists of the N-terminal variable region of the heavy chain (VH), followed by the constant region 1 of the heavy chain (CH1) and the corresponding variable (VL) and CL chain domain. The variable regions are responsible for antigen recognition by interaction of three variable regions of the light and heavy chain, respectively, termed complementarity determining regions (CDRs) [6]. These regions are diversified within B cell maturation by a process called somatic recombination. The CDRs of the heavy chain consist of a variable (V) segment (completely encoding for CDR1 and CDR2) as well as a diversity (D) and a joining (J) segment. Since the junctions of V, D and J are located at the third CDR (CDR3) of the VH domain, this loop displays the region of highest diversity. Light chain genes are recombined by V and J segments only, yielding the three light chain CDRs. The combination of all six CDR loops together form the antibodies 3D-paratope, allowing for highly specific antigen interaction [4], [6].

The sophisticated mechanism responsible for antibody repertoire diversification is described in more detail in the following section.

3.1.2 B cell maturation

B cells begin to develop as pluripotent hematopoietic stem cells (HSC) in the bone marrow, where they differentiate i.a. into multipotent progenitor cells (MPPs), common lymphoid progenitor cells (CLP) and into pro-B cells due to stimuli of stroma cells [7]. These stimuli comprise interactions of specific surface receptors and cytokines as well as chemokines like FLT3-ligand, stem cell factor (SCF) and stromal cell-derived factor 1 (SDF-1), to name a few [8]–[10]. In the early pro-B cells, the expression of proteins responsible for the *Ig* gene rearrangement, e.g. recombination activation genes RAG1 and RAG2, initiates the somatic recombination [11]. Due to specific relocalization of the V, (D) and J segments with successive DNA cleavage resulting in DNA double-strand breaks, the segments are finally joined via non-homologous end joining (NHEJ) enzymes to the final BCR, referred to as somatic recombination or receptor editing process. By V(D)J-gene rearrangement a various number of different antibody coding sequences are formed. Human chromosomes 14, 2 and 22 encode for 38-46 V, 23 D and 6 J segments for the VH domain, 34-38 V and 5 J segments for VL κ as well as 29-33 V and 4-5 J segments for VL λ [12]. Considering a random combination of any V(D)J segment and pairing with either κ or λ , a minimum total number of around 1.5×10^6 distinct antibody sequences can be generated.

To further increase the diversity, within the single V(D)J recombination steps, nucleotide deletions as well as the addition of so called P (palindromic) or N (non-templated) nucleotides can occur, the latter being caused by maturing lymphocyte specific enzyme *terminal deoxynucleotidyl transferase* (TdT) [13].

This complex maturation process results in a vast diversity of different proteins. However, this is only a theoretical number. Many B cells receive apoptotic stimuli because of the random gene rearrangement leading to a non-functional BCR or because of them dying before they encounter their corresponding antigen. Furthermore, due to the random joining of V(D)J segments, BCRs recognizing self-antigens will

occur, which are mostly removed in the bone marrow by clonal deletion or by a secondary receptor rearrangement to prevent self-reactive antibodies circulating in the host [14], [15]. Cells which pass the development checkpoints leave the bone marrow to enter peripheral circulation in secondary lymphoid tissues (SLTs), presenting membrane-bound IgM and IgD isotypes of their specific BCR as naïve B cells. To activate the B cells, an interaction with T helper cells specific for the same pathogen is necessary. Once a B cell encounters its specific antigen, the BCR antigen complex is taken up by endocytosis, degraded and followed by antigen peptide presentation on the surface via major histocompatibility complex (MHC)-II molecules [16]. Those peptide MHC-II complexes are again recognized by T helper cells with their specific T cell receptor (TCR), which respond with the expression of CD40-ligand on their surface as well as the secretion of specific cytokines [17], [18]. These agents promote stimuli for the proliferation, immunoglobulin class switch recombination, somatic hypermutations as well as the differentiation to antibody secreting or long-lasting memory B cells, maintaining the specific pathogen response for repeated infections.

Once differentiated into plasma cells, B cells are able to secrete antibody proteins equivalent to their membrane-bound BCR. These proteins thereby differ by the lack of the transmembrane and cytoplasmic domain but harbor a short amino acid sequence called the tailpiece, which facilitates the secretion of the antibodies.

3.1.3 Somatic hypermutation and class switching

As mentioned above, activation of mature B cells can result in a second stage of diversification, referred to as somatic hypermutations (SHM), comprising a molecular mechanism to further increase the antibody repertoire and to concurrently “affinity mature” the antibodies aiming at a stronger antigen interaction [19]. The B lymphocyte specific activation-induced cytidine deaminase (AID) is thought to be the key enzyme for this process, deaminating cytidines to uracil (C to U) causing an uracil:guanine (U:G) mismatch [20]. This mismatch triggers Ig loci mutagenic processing by base excision repair and mismatch repair pathways evoking transition (C to T) or transversion mutations as well as mutations spread to nearby adenine:thymine (A:T) pairings [21]. However, this AID-mediated process seems not to be completely random but orientates itself to preferentially targeted DNA “hotspot” motifs consisting of several nucleotides, introducing more defined mutations [22].

Furthermore, there is evidence that AID is a crucial component for another DNA alternation process in B cells, changing the constant domain to another isotype, referred to as class switch recombination (CSR) [19], [20]. Within several rounds of cell division, at least partly due to the appropriate activation of AID, CSR as an intrachromosomal deletional recombination event can change the HC from IgM and IgD to other isotypes. To this end, AID deaminates cytidines in HC upstream switch (S) region, consisting of tandem repeats of short G-rich sequences. Deamination needs to occur in both, the S region of IgM as well as of the acceptor isotype, inducing repair processes finally leading to DNA double-strand breaks and NHEJ, explained elsewhere [23]. However, an AID overexpression induces class switch from IgM to IgA without

additional cytokine stimulation, whereas a lack of AID causes a class switch deficiency resulting in a hyper IgM syndrome [24].

The switch to different isotypes creates a variety of antibodies with equal specificity but distinct immune-mediation activities, helping to broaden the immune response against the pathogen and thereby steering function of the antibodies. Additionally, depending on the isotype, partially molecular components are added which support dimerization (IgA) or formation of pentamers and hexamers (IgM) and therefore showing additional effects on e.g. diffusion and avidity. Furthermore, the CH domain influences the stability of the protein, the capability of transcytosis and complement activation as well as the interaction with immune cells via different receptors showing varying affinities for the isotypes. These effector mechanisms are briefly described in the following section.

3.1.4 Effector functions

Upon binding their respective antigen with the Fab moiety, the Fc is accessible for other proteins or immune cells to attach and interact. As already mentioned, depending on the isotype, the interacting components and modes of action differ. Due to binding their complementary structures, antibodies cover the pathogen surface either mark it for immune cells to attack (opsonization), directly neutralize the pathogen, e.g. toxins or viruses, or activate a cascade of plasma proteins, the complement system, which again can directly lyse the pathogen or interact with immune cells [5]. For example, IgM, next to IgG, is primarily responsible for complement-dependent cytotoxicity (CDC). Although IgM, as first isotype of antibodies secreted after an infection, exhibits only moderate affinities, the multimeric structure compensates this issue by the inclusion of avidity effects, simultaneously acting as substantial activation unit for the complement cascade [25], [26]. In contrast, the dimeric IgA is the most predominant isotype in intestinal and respiratory outer mucus layer, crossing the epithelial cells by transcytosis capturing pathogens in mucus to prevent from infections [27], [28], whereas IgE plays a key role in defense against parasites and venoms by interaction with Fc ϵ receptors triggering mast cell and granulocyte activation [29], [30]. However, the major isotype present in the human blood is monomeric IgG. Compared to other isotypes, IgGs exhibit a prolonged serum half-life of about three weeks. Reason for this special pharmacokinetic profile is the antibody recycling mechanism, elicited by interaction with the neonatal Fc receptor (FcRn) [31]. During this process, the IgG antibodies are internalized by cells via endo- or pinocytosis and bind to the FcRn receptor in the acidic environment of the endosomes. The FcRn:IgG complex is then transferred back to the surface where the antibody dissociates due to the physiological pH. Moreover, interactions with additional Fc receptors like Fc γ RI (CD64), Fc γ RII (CD32) and Fc γ RIII (CD16) highlights IgG as important isotype for the activation of innate immune cells resulting in antibody-dependent cellular phagocytosis (ADCP) and antibody-dependent cell cytotoxicity (ADCC) [32]. ADCC is e.g. mediated by natural killer (NK) cells, which express the activating receptor Fc γ RIIIa (CD16a), recognizing IgG-covered cells and resulting in the release of cytotoxic perforins and granzymes as well as

proinflammatory cytokines like interferon- γ (IFN- γ) and tumor necrosis factor α (TNF- α) [33]. Thus, NK cells are important mediators, acting between the innate immunity and the adaptive immune response of the host and will be explained in more detail in the following section.

3.2 Innate immunity

The human defense against invading pathogens is structured in two different, constantly interacting stages, referred to as innate and adaptive immunity, each comprising cellular and non-cellular components to recognize and neutralize foreign structures. Whereas the slower adaptive immune system provides a pathogen-specific, long-lasting response, the innate immune system is less specific but frequently encountered in multi-cellular organisms. It acts as the early stage against pathogen invasions and is constantly present in the organisms, therefore enabling a rapid immune response. Innate immunity comprises continual defense lines like physical barriers of the body and antimicrobial substances as well as inducible protection triggered by immune cells. Skin, respiratory and gastrointestinal epithelium impede pathogens from penetration and express antimicrobial agents as lysozyme and defensins tackling the intruder as a first defense line [34], [35]. Additionally, innate immune cells contribute substantially to the inflammatory response by directly combatting the pathogen as well as supplying crucial stimuli for the activation of the pathogen-specific adaptive immune response. However, in contrast to the highly variable BCR and TCR, innate immune cells like NK cells can bind foreign substances among others via multifarious germline-encoded receptors referred to as pattern recognition receptors (PRRs) These PRRs associate with similar molecular patterns exposed by large groups of pathogens (like polysaccharides in bacterial cell walls) and are named pathogen-associated molecular patterns (PAMPs) [36]. Consequently, the innate immune cells act less pathogen-specific than the adaptive immunity, however, much faster, enabling an immediate suppression of the pathogen.

NK cells, as part of the innate immunity, are also essentially involved in anti-tumor and anti-viral responses [37], [38]. Since the ability of NK cells to mediate strong anti-tumor responses is fundamental for a main part of this work, NK cells will be scrutinized in more detail in the following.

3.2.1 NK cell development

NK cells belong to the innate lymphoid cell (ILC) family and therefore to the lymphatic lineage, like B and T cells, developing from HSCs and MPPs, sharing e.g. functional characteristics but lack of the antigen-specific receptor. NK cells were thought to mature exclusively in the bone marrow, but more recent evidence suggests that SLTs like tonsils, spleen, and lymph nodes play an important role in the NK cell development as well [39]. However, the maturation of NK cells comprises several intermediate stages of development, each dictated by distinct surface markers and stimuli, described in detail by Yu et al. in 2013 and Abel et al. in 2018 [37], [40].

NK cells are classically assigned to the innate immunity because they can perform pathogen-cytotoxic and immune-mediating activities without prior antigen contact, however, they share many attributes to lymphocytes of the adaptive immunity, like education and selection during their maturation as well as the generation of long-lived memory cells following antigen exposure, hence providing the ability to create a secondary recall response, elegantly described elsewhere [41], [42]. An example for this intermediate status of NK cells is the ability to produce INF- γ like ILC1 cells but coincidentally harboring granules releasing cytotoxic perforin and granzymes to lyse target cells, comparable to cytotoxic CD8⁺ T cells [43].

Therefore, NK cells act as discrete effector cells in the innate immunity, enhancing the signals of the early pathogen recognition and mediating an immune response [44]. Because of their multidimensional nature, either secreting proinflammatory cytokines or directly antagonizing altered cells, NK cells represent an important cell population in the immunosurveillance.

The first step to define CLP differentiation into lymphoid lineage is depicted by the expression of interleukin (IL)-7 receptor-alpha (IL-7R α , CD127) in combination with other surface markers. Successive expression of IL-2 receptor β chain (CD122) and transcription factors like E4bp4 (Nfil3) result in the blockade of B cell and T cell differentiation by subsequent transcription factors expression like Id2, thus enabling development into cells of the ILC family [45]–[47]. ILCs do not possess somatic recombined receptors, but express IL-7 receptor, which is also crucial for B cell development. For further differentiation, survival and homeostasis, NK cells require cytokine signals, like IL-2, IL-7 and IL-15, mediated through the common receptor gamma-chain (γ c) family members, as well as stimuli via distinct surface markers either transducing inhibitory or activating signals [40], [48]–[51]. IL-15 was also demonstrated to be crucial for the NK development process itself, since IL-15-deficient mice revealed a severe reduction of functional NK cells [52].

NK cell developmental steps are commonly divided into six linear stages, however, recent evidence suggests a partially more flexible chronology [53], [54]. Nevertheless, the classical description defines HSC, MPP and CLP as the first stages, followed by NK cell developmental intermediates (NKDI) committing the cells to the NK lineage. The single stages are characterized by specified variations of surface marker up- and down-regulation like different C-type lectin superfamily members, e.g. NKG2A and NKG2D, neural cell adhesion molecule (NCAM, CD56), natural cytotoxicity triggering receptor 1 (NKp46, CD335), Fc γ RIIIa (CD16a, for convenience only named further on CD16) and killer-cell immunoglobulin-like receptors (KIRs), to mention a few. Furthermore, CD56 expression levels provide an additional classification of the NK cells based on their functionality [55], [56]. In development stage 5, the NK cell majority downregulates CD56 expression, resulting in the CD56^{dim} subset. About 90 % of the circulating NK cells are designated as CD56^{dim}CD16^{high} and thought to be predominant in cytolytic activities, whereas the CD56^{bright} subset is primarily located in SLTs showing lower levels of CD16 expression (CD16^{low}) and demonstrate superior immunoregulatory capabilities [44], [57], [58]. However, i.a. Fehniger and colleagues could show that the supposedly less-matured CD56^{bright} subset exhibits potent antitumor responses after prior IL-15 sensitization, suggesting a more dynamic functionality classification of matured NK cells as supported by other findings as well [59], [60].

As previously mentioned, surface receptors indicate the various developmental stages of the NK cells. Additionally, members of the surface receptors contribute to NK cell homeostasis and activation by either signaling inhibitory or activating stimuli upon ligand binding, described in the next section.

3.2.2 NK cell homeostasis and activation

NK cells are orchestrated by the integration of signals through inhibitory and activating receptors, building a fine balance for homeostasis [61]–[63]. These stimuli can be triggered by either surface cell ligands, e.g. inhibitory MHC molecules or activating B7-H6, or soluble agents like cytokines and antibodies [64], [65]. Under physiological conditions, human NK cells receive inhibitory signals mainly through interaction of KIRs with self-antigens represented by MHC-I molecules on normal cells. This ability to recognize and therefore distinguish between self and non-self is commonly referred to as “education” or “licensing” of NK cells [66], [67]. The origin model describes the inhibitory signals as more powerful as positive stimuli, hence controlling the NK cell responsiveness. However, the model was modified by Raulet and Vance in 2006 to a “arming” and a “disarming” model [68]. They proposed the need for inhibitory signals via MHC-I interactions to promote NK cell development thereby being responsible for maturation and functionality. Therefore, NK cells lacking MHC-I specific receptors are “disarmed” and hypo-responsive to activating stimuli, as they are not fully matured, resulting in self-tolerance.

Additionally, different theories for the activation of matured NK cells developed. One of the three main theories for NK cell activation is referred to as “missing-self” hypothesis, by which NK cells are activated due to the absence of inhibitory signals provided by, e.g., MHC-I molecules [69]. However, more recent results indicate that additional activating signals are necessary for proper NK cell responses [70]. Moreover, the „non-self“ recognition postulates another hypothesis of NK cell activation due to the identification of cell markers different from the host, e.g. differences in MHC-I molecules due to allogeneic tissue transplants. The third activation thesis is named “induced-self” recognition. Herein, NK cell response is commenced by enhanced activation stimuli with concurrent presence of MHC-I molecules due to the exhibition of a distinct cell surface ligand profile of pre-malignant or stressed cells, which differ from normal cells.

As an example, the “missing-self” recognition occurs within diverse tumors and viral infections, when the expression of MHC-I molecules is downregulated to avoid foreign peptide presentation resulting in cytotoxic T-cells recognition and cell lysis. However, this evading strategy results in an increased NK cell susceptibility, which benefits from the reduced MHC-I related inhibitory stimulus, in turn elevating the activating signals and resulting in an “missing-self” activation [71].

Furthermore, the “induced-self” mechanism is e.g. simulated in diverse therapeutic approaches using immunoconstructs or immunoligands for the NK cell recruitment, thereby mimicking an induced-self condition for a NK cell response [72]–[74].

This specific immune response in the context of NK cell activation comprises the secretion of proinflammatory cytokines INF- γ , TNF- α and granulocyte-macrophage colony stimulating factor (GM-CSF)

as well as lysis of the altered target cell, depending on the NK cell phenotype [56]. Cell lysis is either mediated by specific receptors inducing cell death, discussed in section Inhibitory receptors *FasL* and *TRAIL*, or via NK cell degranulation due to the release of granules containing lytic perforin and granzymes. However, the NK cell activation is only triggered if the activation stimuli exceed the inhibitory ones. To make sure the activation occurs only under specific circumstances like contact to an altered target cell, NK cell activation is tightly regulated by the interplay of a diverse set of distinct inhibitory and activating signals [65].

Because of the variety of different surface receptors on NK cells contributing to their homeostasis, only some of the probably most relevant receptors will be described briefly in the following.

3.2.3 Inhibitory receptors

Receptors contributing to NK cell homeostasis by the mediation of activation-suppressing signals are generally referred to as inhibitory receptors. They act as mediators of negative feedback to prevent from chronic NK activation and immunopathology by the differentiation of self and non-self antigens on autologous cell surfaces facilitating self-tolerance. Upon ligand binding, inhibitory receptors signal through immunoreceptor tyrosine-based inhibitory motifs (ITIMs) in their cytoplasmic tails, causing tyrosine phosphorylation and successive protein tyrosine phosphatases or lipid phosphatases recruitment, which can suppress activation pathway signaling [63], [75]–[77]. Inhibitory receptors on NK cells comprise i.a. programmed cell death protein 1 (PD-1), T cell immunoreceptor with Ig and ITIM domains (TIGIT), T cell surface protein tactile (tactile), NKG2A and several KIRs.

Inhibitory killer-cell immunoglobulin-like receptors (KIRs)

Several members of the KIR group interacting with MHC-I molecules function as important inhibitory receptors on NK cells, as the absence or downregulation of MHC enhances NK cell activation [78]. In more detail, human leucocyte antigen (HLA)-C associates with KIR2DL1, KIR2DL2 and KIR2DL3, while KIR2DL4 recognizes HLA-G. Furthermore, KIR3DL1 binds to HLA-B and KIR3DL2 associates with HLA-A [79]. The underlying nomenclature of the KIR receptors depends on whether two or three extracellular domains (2D or 3D) as well as short or long cytoplasmic tails (S or L) are present. While all inhibitory KIRs contain long cytoplasmic tails bearing ITIM motifs, this description further reveals their functionality, except for KIR2DL4 [79], [80]. In short, inhibitory KIR receptors belong to the Type I transmembrane (TM) receptors possessing extracellular Ig-like domains and long cytoplasmic tails harboring ITIM motifs enabling inhibitory signaling.

Although in vivo studies of the KIR2DL1-3 antibody Lirilumab demonstrated strong blocking effects on KIR interactions with HLA-C expressing tumor cells, clinical trials of acute myeloid leukemia failed to detect

any treatment benefits [81], [82]. A possible reason could be the expression of other essential inhibitory receptors, such as NKG2A.

Natural Killer Cell Receptor Group 2 Member A (NKG2A)

NKG2 lectin-like receptors are expressed as heterodimers with CD94 on NK cells and can either dimerize with NKG2A, forming an inhibitory receptor, or dimerize with NKG2C, leading to an activation signaling. Both receptors specifically recognize HLA-E, a non-classical MHC-I molecule [83]. HLA-E itself binds a restricted subset of peptides derived from classical MHC-I molecules signal peptides, which is necessary for its surface presentation [84]. Thus, employing CD94/NKG2A interacting with peptide complexed HLA-E, NK cells are able to indirectly monitor cell surface expression levels of classical MHC-I molecules. Additionally, besides broad expression on NK cells, NKG2A is present on some T cell subsets, including CD8+ T cells.

Due to the expression on diverse immune cells, the contrary nature of HLA-E as well as its upregulation in diverse tumors, the suppression of the HLA-E/NKG2A interaction represents a possible approach for cancer immunotherapy [85], [86]. Therefore, different xenografts models were developed, in which, e.g., adoptively transferred human NK cells lacking NKG2A expression improved the mouse immunity to human HLA-E expressing sarcoma cells [87]. In addition, preclinical trials with anti-NKG2A Monalizumab exhibited promising results [88], [89]. Therefore, ongoing clinical trials evaluate combinatorial effects of Monalizumab with anti-EGFR (epidermal growth factor receptor) Cetuximab or anti-PDL1 (programmed cell death protein 1 ligand 1) Durvalumab [90], [91].

3.2.4 Activating receptors

The counterparts to the inhibitory receptors are represented by a wide variety of activation-stimulating surface receptors on NK cells. Upon ligand binding, downstream signaling is mediated via different adapter molecules, either containing immunoreceptor tyrosine-based activating motifs (ITAM) like CD3 ζ , Fc ϵ R γ (FcR γ) and TYRO protein tyrosine kinase-binding protein (DAP-12, TYROBP or KARAP) or non-ITAM adapter proteins like DNAX-associated protein of 10 kDa (DAP-10) [76], [92]–[95]. As examples, the activation receptor NKG2D signals through its association with DAP10, which possesses YxxM non-ITAM motif, whereas signaling lymphocytic activation molecule (SLAM) family receptor members like 2B4 use immunoreceptor tyrosine-based switch motifs (ITSM) for signaling, distinct from DAP10 and ITAM YxxL/I motifs. The utilization of different signaling pathways by activating receptors could be a possible explanation for the presence of several members of activation signaling molecules, enabling the mediation of different responses by the NK cells [96]. However, for a sufficient cell response leading to a final NK cell activation, the combination of stimuli by manifold activating receptors are necessary, comprising cell interactions via membrane-bound ligands as well as cytokine stimulation, except for CD16 [65], [77], [97]. Apart from inhibitory receptors, NK cells employ a variety of different germline-encoded activating

receptors, such as, e.g., Fas ligand (FasL), TNF-related apoptosis-inducing ligand (TRAIL), CD16, 2B4, NKG2D or the natural cytotoxicity receptors (NCRs), equipping the NK cells to recognize a plethora of target cell alterations.

FasL and TRAIL

Fas ligand (FasL) and TNF-related apoptosis-inducing ligand (TRAIL), also known as ‘death ligands’, represent a perforin-independent mechanism of NK cells to kill tumor necrosis factor (TNF) receptor superfamily member, commonly known as ‘death receptors’, expressing target cells [98], [99]. Binding of NK cells via these receptors can induce target cells apoptosis, finally causing programmed cell death [100]. FasL expression is restricted to cytotoxic T cells and activated NK cells, whereas Fas is expressed on diverse tissues. Fas protein cross-linking initiates nuclear and cytoplasmic condensation, membrane blebbing, and caspase activation [101], [102].

It was shown that Fas is downregulated in many cancers during tumor progression reducing the susceptibility of tumor cells towards Fas-mediated apoptosis, however, more recent studies showed a selectively cytotoxic effect against oral cancer cells with a low FasL/Fas ratio using a Fas ligand-fused humanized bispecific fusion protein indicating the possibility to use Fas as apoptosis-inducing tumor target [103], [104].

Besides FasL, TRAIL represents another possibility for NK cells to induce target cell apoptosis. It is constitutively expressed by NK cells, either anchored as membrane-bound or released as secreted protein and was shown to mediate spontaneous cytotoxicity against TRAIL receptor (TRAILR1 and TRAILR2) expressing tumor cells due to the mediation of a pro-apoptotic signal through activation of caspases [105], [106].

While rodent tumor models showed promising results, TRAIL death receptor targeting in clinical studies was not able to exhibit satisfying anti-tumor efficacy up to now [107], [108].

NKG2D

NKG2D is a homodimeric activating receptor and member of the C-type lectin superfamily. It is expressed on subsets of T cells as well as on all NK cells and binds to cell surface glycoproteins MHC-I polypeptide-related sequence A (MICA) and MICB as well as UL16 binding proteins (ULBPs; ULBP1 to ULBP6). These ligands are scarcely expressed on healthy cells but can be induced by viral infection, oxidative stress, DNA damage and cell transformation [109], [110]. Upon ligand binding, NKG2D signals through its adapter molecule DAP10 in humans initiating the recruiting p85 subunit of phosphatidylinositol 3-kinase (PI3K) and a complex of growth factor receptor-bound protein 2 (GRB2) and VAV1, finally enabling NK cell degranulation and cytokine production [111].

However, tumors have developed different mechanisms to evade from recognition via NKG2D surface ligand expression. Thus, NKG2D is thought to be important for the early tumor surveillance, since NKG2D-

deficient mice tend to produce spontaneous malignancies, encouraging the suggestion of important early immunoediting events in NKG2D ligands in tumor [112]. Besides immunoediting events causing selection advantages of NKG2D low expressing tumor cells, NKG2D ligands can be shed from the surface. This reduces the expression on tumor cells helping to evade from immune recognition as well as facilitating the downregulation of NKG2D receptors on lymphocytes by endocytosis upon shed NKG2D ligand binding [113]. In contrast to that, evidence of NK activating functions of soluble ligands have emerged in mice promoting tumor control, indicating a more difficult role of shed NKG2D ligands [114].

To avoid shedding, approaches with inhibitor molecules interacting with a disintegrin and metalloproteinase domain-containing protein 10 (ADAM10) and matrix metalloproteinase (MMP) are investigated, aiming at the inhibition of NKG2D ligand shedding from tumor cells [115]. Additionally, recent studies using antibodies addressing the proteolytic site of MICA and MICB proteins, thus fixating the ligands on the cell surface, exhibited preclinical efficacy in diverse tumor models as well as a reduction of lung cancer metastasis [116].

FcγRIII (CD16)

Another important granule-mediated mechanism of NK cell-targeted killing is referred to as antibody-dependent cell-mediated cytotoxicity (ADCC). ADCC is based on the ligation of antibody Fc portions with cognate Fc receptors expressed on the NK cells, whereas the antibodies Fabs confer specificity and affinity towards their antigen. In contrast to other lymphocytes, NK cells express only activating Fc receptors, namely FcγRIIIa (CD16) and FcγRIIC (CD32c), and therefore are considered to be important ADCC effector cells [117]. While CD16 is expressed by most NK cells, CD32c is present on NK cells in only 7 to 15 % of healthy individuals (as a result of a single-nucleotide polymorphism (SNP)) [118]. A single SNP is also responsible for genotypic variations of the expressed FcRs on NK cells, for instance resulting in CD16 polymorphic variants either harboring a phenylalanine (F) or a valine (V) at amino acid position 158. This amino acid exchange influences the affinity of CD16 to immunoglobulins, leading to an improved clinical outcome for patients with homozygosity for the higher affinity V genotype compared to F/V heterozygous or F/F homozygous individuals if treated with therapeutic monoclonal IgGs [119]–[121].

ADCC was initially described as secretion of cytotoxic perforin and granzymes leading to the lysis antibody-coated target cells following ligation of CD16 by IgG target cells. Nowadays, ADCC is understood and used as a multi-tiered process involving coordinated immune cells with distinct functionalities. In case of NK cells, ADCC can induce different effector pathways including cytotoxic granule exocytosis and the release of proinflammatory cytokines, such as TNF- α and INF- γ without costimulation necessary for other receptors to sufficiently activate NK cells [122]. CD16 harbors only a short cytoplasmic tail lacking ITAM motifs, thus depends on the association with homodimers or heterodimers of adaptor molecules CD3 ζ or Fc ϵ R1 γ within the cell membrane for appropriate activation signaling [123]. CD16 association with an immunoglobulin Fc portion thereby initiates the signal transduction mechanisms of NK cells comprising phosphorylation of the ITAM motifs on the adapter molecules cytoplasmic tails, binding of tyrosine kinases

ZAP-70 and Syk as well as activation of PI3K, NF- κ B and ERK pathways, finally resulting in NK cell degranulation and cytokine secretion [124].

Until today, many monoclonal antibody therapies addressing distinct tumor targets like Rituximab (anti-CD20), Trastuzumab (anti-HER2), Cetuximab (anti-EGFR) and Daratumumab (anti-CD38) are used as standard of care treatments for tumors and hematological malignancies, emphasizing the important role of ADCC in mediating anti-tumor effects [33], [125]. Furthermore, different antibody-derived platforms like bispecific killer engagers (BiKEs) or trispecific killer engagers (TriKEs) have developed applying anti-CD16 moieties for ADCC mediation on NK cells, even with some proteins in ongoing clinical studies [126]–[128]. Analogous to NKG2D, CD16 was reported to be shed by NK cells due to activities of a disintegrin and metalloprotease, ADAM17. It was shown that inhibition of the metalloprotease and thereby consistent CD16 expression on NK cells resulted in a notable increase of intracellular cytokines. In contrast to that, the effect on degranulation and cytotoxicity was less [129]. This result was supported by Davis and colleagues in 2018, who revealed that CD16 shedding facilitates NK cell detachment from target cells, supporting NK cell motility and serial engagement of target cells [130]. Taken together, a higher expression of CD16 on NK cells seems to trigger more cytokine production, whereas lower surface expression of CD16 may be beneficial for NK cell serial killing.

Natural cytotoxicity receptors (NCRs)

The natural cytotoxicity receptors (NCRs), comprising three Type I TM receptors belonging to the immunoglobulin superfamily, were identified in the late nineties of the last century by their ability to recognize and lyse tumor cells by human NK cells [131]–[133]. The receptors NKp30 (NCR3; CD337) and NKp46 (NCR1; CD335) are constitutively expressed on resting NK cells, while NKp44 (NCR2; CD336) requires NK cell activation for its expression. Even though the NCRs belong to the same immunoglobulin superfamily and perform similar functions, crystallographic characterization of the NCRs revealed considerable differences between the three receptors regarding their amino acid sequence and structure [134]. While NKp46 contains two extracellular Ig-like domains, NKp30 and NKp44 possess only one Ig-like domain responsible for ligand binding. All three NCR ectodomains consist of a membrane-proximal stalk domain and the distal ligand-binding domain. The ectodomain is suggested to possess multiple interaction sites to explain how the NCRs can interact with structurally diverse ligands. Positively charged amino acid residues in their inherent C-terminal TM domains form a salt bridge with a corresponding residue in the associated TM domains of the ITAM adaptor molecules necessary for signal transduction. NKp44 is the only NCR which associates with DAP-12, whereas NKp46 and NKp30 attach to CD3 ζ or Fc ϵ RI γ forming heterotrimeric structures for downstream signaling [124].

Although the NCRs have been known for over twenty years, their ligands are less well characterized than those of other receptors. Hence, a lot of efforts have been made in the last years to identify ligands for these three activating receptors. These comprise viral-, bacterial- and parasite-derived structures as well as cellular ligands on stressed or tumorous cells which are barely expressed on healthy tissue [135], [136].

This diverse ligand profile opens a wide field for possible therapeutic applications addressing NK cells due to their NCR receptors.

NKp46

The NKp46 encoding gene, NCR1, is located in the tail of the leucocyte receptor complex on chromosome 19, and the translated protein is the main NK cell lineage-defining activating receptor in mammals, whose triggering culminates in degranulation and the release of proinflammatory cytokines [136]. NKp46 was the first NCR identified and exists in several isoforms [137], [138]. Although NKp46 is primarily present on NK cells, some other cell populations were found expressing it as well. These include $\gamma\delta$ T cells, ILC1 and a subset of group 3 ILCs as well as some other discrete T cell sets [139]–[143].

In contrast to NKp44 and NKp30, an NKp46 orthologue was identified in mice, allowing for in vivo assessments of this protein entitled NCR1 (mNKp46). Thus, Mandelboim and colleagues were able to generate NCR1 knockout mice by the replacement of NCR1 exons with a GFP reporter cassette. These mice died rapidly due to influenza virus infections and exhibited an increase in tumor metastasis [144], [145]. Additionally, other mutant mice were generated via random mutagenesis on this receptor, exhibiting increased resistance to viral infections due to hyperresponsive NK cells because of a mutation in the NCR1 gene [146]. These observations show the important role of NKp46 for the immunosurveillance. However, NKp46 is also associated with NK and T cell lymphomas and suggested to be involved in diabetes [147]–[149]. For these NKp46-dependent diseases, in vitro studies of anti-NKp46 antibodies were recently published, implying possible treatment options [150], [151].

To date, many distinct ligands from different pathogenic origins are described to associate with NKp46 in an NK cell-activating manner. It was shown that NKp46 binds hemagglutinin and hemagglutinin-neuraminidase of diverse viruses as well as bacterial structures like vimentin expressed on *mycobacterium tuberculosis*-infected cells, inducing a NK cell-mediated lysis of these cells [152]–[156]. Furthermore, NKp46 ligands have been reported to be expressed on different tumors [145], [157].

Therefore, NKp46 is used as a target for immunostimulatory approaches, by either expressing its ectodomains as chimeric antigen receptor on (CAR) T cells or by using an anti-NKp46 antibody entity as part of NK cell engagers (NKCEs) [158], [159].

NKp44

NKp44, in contrast to NKp30 and NKp46, is not constitutively expressed by resting NK cells, but is upregulated on NK cells if stimulated, e.g. with IL-2, IL-15 or IL-1 β [160], [161].

NKp44 is encoded by the NCR2 gene located in the triggering receptors expressed on myeloid cells (TREM) receptor locus on chromosome 6 [162]. Transcription of the NCR2 gene translates into three expressed variants, termed NKp44-1, NKp44-2 and NKp44-3. Whereas NKp46, NKp30 and variants NKp44-2 and NKp44-3 harbor only short cytoplasmic tails lacking signaling motifs, only the cytoplasmic domain of

NKp44-1 contains an ITIM motif typical for NK cell inhibitory receptors. Thus, NKp44-1 provides the potential of imparting suppressing as well as activating signals as it can still couple with DAP-12 [135]. Like the other NCRs, NKp44 is also expressed on sets of distinct ILCs and diverse T cells.

Several ligands of NKp44 have been identified, comprising primary flavivirus-derived and cellular molecules. For example, NKp44 binds specifically to envelope proteins of the *West Nile virus* (WNV) and *Dengue virus*, since WNV-infected cells stimulated NK cell degranulation and IFN- γ secretion in an NKp44-dependent manner [163]. Furthermore, a new exon of the usually nuclear mixed-lineage leukemia protein-5 (MLL5) resulting in a protein variant with an altered C-terminal amino acid sequence, hence aberrantly expressed on tumors or virus-infected cells but not on healthy tissue, was identified and termed NKp44 ligand (NKp44L) [164]. As another NKp44 ligand, Nidogen-1 (NID1 or Entactin) usually functions as extracellular matrix linker, stabilizing and assembling the basement membrane. If present in soluble form, this ligand might impair NK cell function as seen in serum from patients with ovarian and lung cancer [165], [166].

NKp30

NKp30 is encoded by the NCR3 gene located in the highly polymorphic telomeric end of the class III region of human MHC locus. Its transcription generates several mRNA splice variants finally translated into three constitutively expressed isoforms NKp30a, NKp30b, and NKp30c, which differ in length of their cytoplasmic domain [135]. Out of all, NKp30a and NKp30b are the ones which act immunostimulating, whereas NKp30c is found to be immunosuppressive [167]. Although the isoforms are concurrently expressed on NK cells, the canonical role for the dominant splice variant is NK cell activation culminating in cytokine release and degranulation. Besides NK cells, NKp30 is expressed on other lymphocytes like a set of CD8+ T cells, expanded peripheral blood $\gamma\delta$ T cells (V δ 1+) and umbilical cord blood T cells cultured in IL-15 [168]–[170].

To date, several ligands for NKp30 are known, comprising viral structures like hemagglutinin of human vaccinia virus or human cytomegalovirus protein pp65, both acting as antagonists, or the parasites Duffy binding-like-1 α domain of *Plasmodium falciparum* erythrocyte membrane protein-1, which mediates NK cell lysis of infected cells [171]–[173]. Furthermore, fungal structures such as β -1,3 glucan of *Cryptococcus neoformans* and *Candida albicans* as well as cellular ligands, e.g. B7-H6, which is upregulated in altered and stressed cells, induce direct killing by NK cells via NKp30 engagement [174]–[176].

Interestingly, there is evidence that the stalk domain of NKp30 contributes to the ligand binding and increases its affinity for cellular ligands BAG6 and B7-H6 [177], [178].

Furthermore, it has been shown that NKp30 is a promising receptor for immunostimulatory approaches, enhancing immune engagement by increased NK cell-mediated target cell cytotoxicity via combination of therapeutic antibodies with recombinant immunoligand B7-H6, generation of CAR T cells based on NKp30 receptor or, as recently published, incorporating anti-NKp30 antibody entities in TriKEs [179]–[183].

B7-H6 as natural ligand of NKp30 is another essential part of this work, therefore, this protein is described in more detail within the next section.

3.3 B7-H6

Natural cytotoxicity triggering receptor 3 ligand 1, also known as B7-H6 (or B7H6). is a natural ligand of NKp30. B7-H6 belongs to the B7 family and possesses two extracellular Ig-like domains similar to other members of this group, which can be divided into a membrane distal Ig variable-like domain and membrane proximal Ig constant-like domain [184]. For the association, the front and back β -sheets of the NCR interact with the cognate CDR-like loops of B7-H6 variable-like domain, thus engaging B7-H6 in an antibody-like manner.

Besides expression on a wide range of tumor cells and on a small set of proinflammatory monocytes and neutrophils upon stimulation with proinflammatory cytokines such as IL-1b and TNF- α or ligands of Toll-like receptors, B7-H6 expression on healthy cells is found to be neglectable [176], [185].

Additionally, B7-H6 expression is upregulated on cells as reaction to disfunctions such as endoplasmic reticulum stress or due to cancer treatment with chemotherapy, targeted therapy or radiation therapy after initial tumor evasion, to serve as mode of immunosurveillance, thereby turning immune-cold into immune-hot tumors [186], [187].

In contrast to the B7-H6 surface expression upregulation, mechanisms of NK cell evasion by B7-H6 downregulation have been found in virus infections like human cytomegalovirus and human herpesvirus 6 [188], [189]. Similarly, some tumors use metalloprotease-mediated shedding of B7-H6 from their surface to escape immune cell recognition, which is also associated with reduced NKp30 expression and dysfunction due to chronic engagement of NK cells, resulting in poor patients' overall survival [190], [191]. Furthermore, soluble B7-H6 was detected in the sera of patients with gram-negative sepsis suggesting a B7-H6-dependent NK cell inhibition during inflammation [185].

However, it was demonstrated that the engagement of NKp30 upon B7-H6 binding is sufficient for NK cell activation resulting in degranulation and secretion of proinflammatory cytokines, as shown by NKp30-dependent NK cell-mediated killing of B7-H6 expressing human erythroleukemic K562 cells [176].

For this reason and the aforementioned restricted expression on stressed cells, NKp30 engagement via B7-H6 seems to be a promising approach for possible immunotherapies. To this end, conceptual approaches were evaluated by Peipp and colleagues involving the fusion of B7-H6 ectodomain to an antibody single chain variable fragment (scFv) either addressing human epidermal growth factor 2 (HER2) on HER2-positive breast cancers or targeting CD20 on B cell lymphomas, revealing specific target-dependent cellular cytotoxicities [72], [179], [180].

Based on these results and the observations of Yili Li et al. [184], who determined a low affinity of B7-H6 to its cognate receptor NKp30 with a dissociation constant of approximately 1 μ M, one major task of this study was to assess if an increased affinity of B7-H6 to NKp30 translates into an improved NK cell-mediated cytolyse using a bispecific antibody-like scaffold.

3.4 Surface display systems

A modified version of the following section has been submitted by our group and has recently been accepted for publication as book chapter in *Introduction to Antibody Engineering* Rümer & Wozniak-Knopp (eds) (see chapter 6.5 and 7.5)

Besides Hybridoma technology, which still remains state-of-the-art in antibody hit discovery, several display technologies have emerged during the last decades that were inspired by the work of Köhler and Milstein, who fused single antibody expressing B cells with immortal myeloma cells, resulting in culturable monoclonal antibody (mAb) expressing hybridoma cells [192].

Until now, distinct display systems have been described, comprising non-cellular systems like mRNA display, ribosomal display and DNA display, as well as cellular systems like phage display and yeast surface display. The most essential feature of these in vitro selection platforms relies on genotype phenotype coupling, allowing for backtracking of the represented protein selected by its biophysical properties to its genetic code. Thus, all display systems simulate the B cell maturation cycle in vivo, aiming at the amplification of desired candidates matching the requirements. Since display systems have been developed for more than thirty years, they can be applied for manifold and complex approaches like affinity maturation, screening for pH-sensitive binding or for peptides recognizing chemical modifications, small molecules or toxins [193]–[195]. However, the identification of appropriate proteins with prescribed properties via surface display methodologies still remains laborious and challenging, since large diversities created by either naïve, immunized or synthetic repertoires need to be screened [196].

3.4.1 Phage Display

Based on the idea of George P. Smith, who fused the genetic code of oligo-peptides to the minor coat protein III (pIII) gene of filamentous *E. coli* phage M13, Sir Gregory P. Winter refined this methodology for antibody engineering, thereby generating the first and still most frequently used in vitro selection system named phage display [197].

In the classical phage display approach, the initial step is the library construction. For this, the desired proteins, e.g. antibodies, are cloned as a protein::pIII fusion into a plasmid, referred to as “phagemid” in *Escherichia coli* (*E. coli*). By separating the protein::pIII fusion from other cis-acting elements for phage replication and packaging, a more flexible system was achieved. Most of the phage display systems available today still rely on the classical fusion to pIII, thus reflecting the robust and versatile system of the protein::pIII fusion [198].

After cloning, the resulting *E. coli* library is infected with helper phage providing the necessary components for final assembling of the phagemid into phage particles and subsequent protein display on their surface [198], [199]. This crucial step for protein presentation on the phage surface was significantly enhanced by Dübel and colleagues, who developed an improved helper phage system, the so-called “hyperphage” [200].

When the phagemid containing bacteriophages display the translated fusion proteins on their surface, the “panning” step is employed, meaning that the bacteriophages displaying the respective library candidates are incubated with immobilized antigen. While the antigen-specific variants associate with the target protein, the unspecific molecules are removed by washing steps. Within this process, chemical, biological and physical parameters, such as pH, competitor or temperature, can be adjusted, to force the isolation of protein with desired properties. After elution of the antigen-specific bacteriophages, *E. coli* cells are infected once more, enabling the amplification of the enriched protein candidates for iterative phage display rounds.

Phage display allows for the rapid generation of libraries in the range of more than 10^{11} variants and the utilization of different antibody scaffolds [201]–[206]. However, due to the utilization of a prokaryotic folding machinery in *E. coli*, the production of complex structures like full-length antibodies remains challenging.

Until today, phage display enabled the isolation of several biologics which are in clinical and preclinical stages or even been granted market approval [207]. As an example, the commercially most successful fully human antibody Adalimumab was engineered by phage display, as was the 2011 by FDA-approved B cell-activating factor inhibiting antibody Belimumab [208], [209].

3.4.2 Yeast Surface Display

The yeast surface display (YSD) technology was described for the first time by Boder and Wittrup in 1997. This process utilizes the eukaryotic yeast strain *Saccharomyces cerevisiae* for the cell surface display of the protein of interest (POI) [210]. The expression of the POI is mediated by the genetical fusion to surface anchor proteins like α -agglutinin of *S. cerevisiae*, which normally mediates cell adhesion contact to other yeast cells during the mating process [211], [212]. This glycoprotein consists of two subunits, of which Aga1p is linked to the cell membrane via a glycosylphosphatidylinositol (GPI) anchor and is covalently linked to subunit Aga2p by two disulfide bridges [213]. Fusion of the POI to subunit Aga2p consequently enables the surface presentation and attachment to the yeast cell surface. To reliably induce the expression of the POI on the yeast cell surface, Boder and Wittrup developed a system well established today, in which the expression of both Aga1p, integrated in the yeast genome, as well as Aga2p, linked to the POI and expressed from a display plasmid, is controlled by a galactose-inducible promotor.

Due to the eukaryotic background of yeast cells, which provides an adequate protein-folding machinery, even more complex structures like whole IgG1 antibodies can be displayed [214]. Additionally, other structures like antibody scFv, Fabs or Nanobodies can be presented on the cell surface [215].

Initially, a diversity of the POI is used for the transformation of yeast cells, followed by a cell metabolism switch due to a change of the carbon source glucose to galactose, thereby inducing the POI expression. Then, the yeast cells can be screened via FACS for cells displaying an POI with desired properties, which represents another advantage of YSD over classical biopanning. Typically, in FACS screenings, distinct fluorescence dyes are used for antigen labeling as well as dyes to check the protein display on the yeast

cells by, e.g., genetic implementation of a HA tag into the expression plasmid and the use of fluorescently labeled antibodies directed against it. These dyes can be detected simultaneously, thus allowing for the detection as well as quantification of the fluorescence signals from each yeast cell, further enabling the collection of double positive cells (antibody-presenting and antigen-binding) [216]. During several rounds of sorting, the antigen-specific diversity can be increased. Further, by adjusting the sorting stringency via, e.g., gating strategy or a decrease in antigen concentration, cells matching predefined characteristics such as high-affinities variants can be enriched [217]. The applicability of YSD for affinity maturation was already demonstrated by Boder and Wittrup in 1997 with studies on a fluorescein-binding scFv and further validated by Wittrup and colleagues in 2000 with the identification of an antibody with affinities among the highest reported so far [210], [218].

Besides the maturation of antibody affinities, YSD was utilized to enhance the affinity of ligands to their cognate receptors, such as epidermal growth factor (EGF) or interleukin-2 (IL-2) with affinities increased up to thirtyfold for EGF receptor and IL-2 receptor alpha subunit, respectively, or an affinity enhanced approximately up to 50,000-fold of a signal-regulatory protein α (SIRP α) variant to the integrin associated protein (IAP, CD47), giving clear evidence that YSD application is not restricted to antibody scaffolds [219]–[221].

3.5 Bispecific antibodies and immunoligands

As briefly mentioned in chapter 3.4, Köhler and Milstein provided the basis for modern immune therapies with their research on mAb production, paving the way for more than 80 antibody therapeutics which have been granted market approval until today [222].

However, due to their monospecific structure enabling the binding of only one target, mAbs provide only a constrained mode of action limiting their efficacy in complex, multifactorial-originated diseases [223], [224]. To this end, more flexible and multi-specific scaffolds, such as bispecific antibodies (bsAbs), were developed, of which three bsAbs have already been granted market access and over 85 are under clinical investigation (as of 2019) [225]–[227].

As another possible therapeutic approach, bispecific immunoligands emerged, comprising at least one natural ligand-derived entity, whereas bsAbs comprise two physically connected single-binding antibody moieties enabling the simultaneous binding of two different structures [74], [228]. The choice whether to employ a bsAb or bispecific immunoligand as well as the final molecule format thereby influences its properties regarding processability, pharmacokinetics and pharmacodynamics [226], [229]–[231]. The latter, for instance, is suggested to be influenced by size and affinity of the bispecific molecules, altering shape and duration of the immunological synapse. [232]–[234].

All these bispecific proteins allow applications like addressing of distinct epitopes, blocking of different disease mediators or recruitment of immune cells to a specific target, which was, e.g., shown to receive curative outcomes for patients with minimal residual disease B cell precursor acute lymphoblastic

leukemia by treatment with bispecific T cell engager Blinatumomab [235], [236]. Besides T cells, other immune cells like NK cells can be exerted for this approach of immune cell redirection, which was, e.g., utilized by Peipp and colleagues employing bispecific immunoligands, exhibiting promising in vitro results [72], [179], [180]. In these studies, tumor-associated antigens targeting scFv antibody moieties were physically connected to NK cell activation receptor binding ligands. The advantage of these “Fc-less” formats relies on their small size allowing better tissue penetration as well as facile manufacturability due to expression of a single polypeptide chain. But the lack of the Fc portion is yet the main drawback of these bispecifics, as they cannot provoke Fc-mediated effector functions like ADCC or FcRn recycling, thereby evincing shorter plasma half-life influencing their therapeutic activities [237]. In contrast, the IgG-based bispecific constructs incorporating antibody Fc portions show prolonged half-life but struggle with mispairing of heavy chains (HCs) and light chains (LCs) during expression. To bypass this issue, different techniques evolved, which are explained elsewhere [226], [227], [238].

To overcome HC homodimerization in IgG-based bispecific molecules consisting of two distinct “half” antibodies each comprising a single HC and cognate LC to form the specific paratope, strategies like “knobs-into-holes” (KiH) or Strand-Exchange Engineered Domain (SEED) were developed. To force HC heterodimerization, KiH utilizes the introduction of bulky amino acid residues to one HC to form a “knob” and smaller residues on the opposite chain creating the shape of the complementary “hole” [239]. In contrast, by engineering of alternating IgA and IgG segments in the CH3 domains of both HCs, the SEED technology allows for heterodimerization due to the assembly of the resulting anti-parallel CH3 domains [240], [241].

Besides the homodimerization of HC, the two different LC in classical Fab-derived IgG-like bispecific antibodies can lead to mispairings, resulting in loss of affinity or even abrogation of antigen binding. This issue can be addressed by the incorporation of artificial, non-native linker sequences, connecting the heavy and light chain, like in scFv or scFab formats [242]. Another approach is based on domain crossover of CH1 and CL in a Fab moiety to obtain correct LC pairing, referred to as CrossMab [243].

A more extensive technology employs transgenic rodents, e.g. OmniFlic® rats, harboring a full human antibody VH diversity but only a single functional “common” LC [244]. Consequently, a bispecific antibody can be produced with only one LC, bypassing the LC mispairing issue. Besides these briefly described examples, other technologies for correct LC pairing have been developed, which are described elsewhere [238].

Additionally, another approach circumventing HC homodimerization and LC mispairing is the utilization of camelid nanobodies (VHH)- or VH-based IgG-like bispecific antibody platforms [245], [246]. The exchange of the antibodies VH and VL by VHH domains creates a bispecific antibody without the need of VL contribution. Hence, if expressed as IgG-like protein, a bispecific bivalent molecule with an intact Fc portion is formed. It was recently shown by our group that even a one-armed molecule of this format, thereby possessing monovalent bispecificity, was able to recruit and activate NK cells [246].

4 Objectives

Since the groundbreaking invention of the hybridoma technology in 1975 by Köhler and Milstein, extensive studies have enabled the generation of antibodies for distinct applications, such as laboratory and diagnostic tools and as therapeutic entities. Nowadays, a plethora of possibilities is available for the creation of different antibody and antibody-like structures, regarding their origin, format and biophysical properties, to name a few. Alongside, technologies facilitating the identification of specific antibodies with desired properties evolved, allowing for screenings of diversities obtained from immune, naïve or (semi-)synthetic libraries. However, search for appropriate antibodies during the pre-clinical phase still remains laborious and challenging. One aim of this study was the expansion of the existing phage and yeast surface display technology to streamline the hit-discovery process by the implementation of an optimized library generation approach. For this purpose, the *Golden Gate Cloning* (GGC) methodology was utilized for the generation of a combinatorial antibody library in a one-step process, bypassing the classical multi-step process for library generation. In more detail, the common approaches for the generation of combined VH and VL repertoires for phage and yeast surface display rely on execution of several successive cloning steps. One objective of this work was the simplification of this process by the application of a “one-pot” GGC reaction, while maintaining quality standards such as library functionality and number of hits. Moreover, the applicability of this optimized library generation approach should be tested for the facile generation of distinct antibody formats as well as different diversity sources.

The discovery of unique camelid heavy chain antibodies (hcAb) and their binding domains, referred to as nanobodies or VHHs, enables the generation of mono- and bispecific antibody structures devoid of light chains. In this context, Baty and colleagues published a proof of concept bispecific VHH-based Fab-like format utilizing the constant domains C_κ and CH1 of IgG as natural dimerization domains in 2013. According to this, IgG-like SEED bispecific VHH-based antibodies were created within this work via the replacement of VH and VL by different VHH domains. This allows the generation of full-length bi- and trispecific antibodies with adjustable valences for their cognate antigens. The generation and assessment of this novel VHH-antibody platform regarding its processability and biophysical properties of antibodies created was another aim of this work. Furthermore, the applicability of these molecules in the context of immune cell recruitment towards tumor cells should be examined in this work with exemplarily chosen immune therapy-relevant NK cells.

With respect to immune cell recruitment, bispecific immunoligands have attracted continual interest besides bsAbs, especially for the redirection of NK cells in cancer indications. It has been shown by Peipp and colleagues that NK cells can be recruited and simultaneously activated by the engagement of Nkp30 via its natural ligand B7-H6 if used as bispecific immunoligand. It was also described by other groups that YSD has been successfully applied for the affinity maturation of polypeptides different to antibody molecules. Another essential part of this study was the affinity maturation of B7-H6 via YSD and the

assessment of the hypothesis that increased affinity of B7-H6 for NKp30 may translate into an enhanced NK cell cytotoxicity as well as an augmented secretion of proinflammatory cytokines.

Facile generation of antibody heavy and light chain diversities for yeast surface display by Golden Gate Cloning

<https://doi.org/10.1515/hsz-2018-0347>

Received August 15, 2018; accepted November 11, 2018; previously published online November 17, 2018

Abstract: Antibodies can be successfully engineered and isolated by yeast or phage display of combinatorial libraries. Still, generation of libraries comprising heavy chain as well as light chain diversities is a cumbersome process involving multiple steps. Within this study, we set out to compare the output of yeast display screening of antibody Fab libraries from immunized rodents that were generated by Golden Gate Cloning (GGC) with the conventional three-step method of individual heavy- and light-chain sub-library construction followed by chain combination via yeast mating (YM). We demonstrate that the GGC-based one-step process delivers libraries and antibodies from heavy- and light-chain diversities with similar quality to the traditional method while being significantly less complex and faster. Additionally, we show that this method can also be used to successfully screen and isolate chimeric chicken/human antibodies following avian immunization.

Keywords: antibody discovery; chimeric antibodies; gap repair cloning; Golden Gate Cloning; human antibodies; yeast mating.

Introduction

Monoclonal antibodies are among the most successfully applied molecules for biomedical as well as biotechnological applications (Carter and Lazar, 2017; Kaplon and Reichert, 2018). Their high affinity and specificity towards an antigen combined with effector functions is rendering antibodies efficacious for the treatment of various diseases such as immunological disorders or cancer. Nowadays, more than 50 antibodies are clinically available and a multitude of different molecules is currently investigated in late stage clinical trials or is undergoing regulatory review (Chung, 2017; Kaplon and Reichert, 2018). With regards to antibody discovery, it has been known for quite some time that yeast surface display (YSD) is a powerful platform technology for the identification of antibodies and for engineering purposes (Boder and Wittrup, 1997; Feldhaus et al., 2003; Doerner et al., 2014; Yang et al., 2018). Consequently, a plethora of different antibodies and antibody-based constructs was engineered using YSD (Wozniak-Knopp et al., 2010; Zielonka et al., 2014; Schröter et al., 2015; Wang et al., 2016; Könnig et al., 2017; Krahl et al., 2017; McMahon et al., 2018). It was recently shown by Nozach and co-workers that in comparison to scFvs or single chain Fab moieties the Fab format is most efficient in expressing functional antibodies on the surface of the yeast, supporting the notion that Fab fragments more closely resemble the classical antibody structure (Sivelle et al., 2018). One prominent approach for the generation of YSD Fab libraries is the individual generation of heavy and light chain encoding plasmids in haploid yeast strains via a homologous recombination-based process referred to as gap repair cloning. Afterwards, these yeast cells are combined by yeast mating (YM) into diploid cells that display functional antibody fragments (Weaver-Feldhaus et al., 2004). We have previously described an alternative one-step strategy by utilizing Golden Gate Cloning (GGC) for library construction (Rosowski et al., 2018). Pioneered by Marillonnet and colleagues, this technology makes use of type II restriction enzymes that have non-palindromic recognition sites and cut outside of their recognition

sequence (Engler et al., 2008). Therefore, restriction site overhangs (herein termed signature sequences) can be designed by purpose, allowing for cloning in a one-pot reaction in a unidirectional manner with deletion of the recognition sites during the reaction. We showed that the heavy and light chain of a Fab can be simultaneously cloned into the final display vector in a single step, significantly reducing the complexity of library establishment (Rosowski et al., 2018). Subsequently, we demonstrated that this approach is versatile for the isolation of common light chain antibodies from heavy chain diversities only. However, the generation of classical antibody Fab libraries with adequate qualities is more sophisticated, as heavy as well as light chain diversities need to be incorporated properly. Such GGC-based libraries were recently constructed efficiently using phage display as the platform technology (Nelson and Valadon, 2017).

In this work we aimed at comparing the library construction process and selection output of the GGC-based methodology with the classical approach of YM. To this end, transgenic rats comprising a partial human VH and VL repertoire were immunized with CEACAM6, an antigen overexpressed in many tumors (Lewis-Wambi et al., 2008; Zhang et al., 2014; Rizeq et al., 2018). From the same starting material, GGC-based (Figure 1) as well

as YM-based libraries were constructed and compared in terms of library size and immunoglobulin gene repertoire usage. In order to isolate antigen-specific clones, both libraries were sorted against recombinant CEACAM6 protein. Afterwards, the sorting output from both libraries was analyzed with respect to sequence diversity and representative clones identified were characterized in terms of affinity.

Additionally, we also set out to demonstrate a broader applicability of this GGC-based approach. For this, wild type chickens were immunized with epidermal growth factor receptor (EGFR) as well as human chorionic gonadotropin (hCG) and chimeric chicken/human antibody YSD libraries were constructed in which the chicken VH and VL repertoires were grafted onto human domains CH1 and CL1. EGFR is overexpressed in many human cancers, such as colorectal and head and neck cancer (Sigismund et al., 2018). hCG is being used as earliest indicator of pregnancy by detection of this glycoprotein hormone in the urine (Braunstein et al., 1976). Due to their phylogenetic distance from humans, such chicken antibodies are interesting for biotechnological applications, as they allow for the generation of antigen-specific moieties recognizing conserved epitopes on mammalian targets (Davies et al., 1995; Abdiche et al., 2016). We show that a diverse set of

antigen-specific chimeric antibodies can be obtained by library sorting against both antigens.

Results

Design of library components

In this study, we aimed at comparing the library generation process as well as the selection output of a GGC-based yeast surface display library approach with the conventional (YM) three-step method of individual heavy and light chain sub-library construction followed by YM. For the GGC-based library components, we decided to adopt the two-directional design as previously published by our group (Rosowski et al., 2018). Here, four different modules were utilized, a destination plasmid, an entry plasmid comprising *GAL1/GAL10* promoters for bidirectional expression of heavy and light chains as well as signal sequences for antibody secretion and both, the heavy and light chain variable region modules, i.e. the PCR amplified VH and VL repertoire with flanking type IIIs restriction sites (*BsaI*) and signature sequences for directional cloning. The destination plasmid was essentially composed of a tryptophan marker for vector selection, a *CL λ* domain as well as a CH1 region that is fused to *Aga2p* enabling Fab surface display. In general, signature sequences were part of antibody constant regions or signal sequences (Figure 1B). All restriction sites were designed to be removed during the restriction-ligation reaction, allowing for one-step cloning.

In order to compare the GGC-based method with the mating-based approach according to Weaver-Feldhaus et al. (Weaver-Feldhaus et al., 2004), a two-vector based system for heavy- and light chain expression was utilized. Expression of both chains was mediated by the *GAL1* promoter. The heavy chain plasmid encoded for a signal peptide, followed by a stuffer for VH gap repair cloning as well as by domain CH1 fused to *Aga2p*. Additionally, this vector comprised a tryptophan auxotrophic marker. Akin to this, the light chain encoded for a signal peptide followed by a stuffer and *CL λ* as well as for a leucine marker gene (Krah et al., 2017).

Library construction, analysis and selection of CEACAM6-specific antibodies

Transgenic rats harboring human antibody variable regions, referred to as OmniRats (Osborn et al., 2013) were

DNA-immunized with CEACAM6. After immunization, lymph nodes were resected, and total RNA was extracted followed by cDNA synthesis (Figure 1A). For both libraries, VH and VL repertoires were amplified in two consecutive PCRs. In the first PCR, the different forward primers annealed in the leader of heavy and light chain V-genes whereas the reverse primer annealed in region CH1 or CL λ . The resulting product served as template material for the GGC as well as the YM approach. The second PCR was carried out to incorporate *BsaI* sites and signature sequences for the GGC approach or to introduce homologous sites for gap repair cloning into the two-vector system of the YM approach.

With respect to GGC, a one-pot restriction-ligation reaction was performed and the resulting expression plasmid comprising heavy and light chain combinatorial diversities was transformed into *Saccharomyces cerevisiae* strain EBY100, yielding a calculated library size of approximately 2.9×10^9 independent clones. For the YM-based method, heavy and light chain variable regions were separately incorporated into linearized YSD plasmid in a homologous-repair mediated process named plasmid gap repair. The yeast strain EBY100 (haploid, mating type a, MATa) was utilized for gap repair cloning of the heavy chain repertoire, whereas BJ5464 cells (haploid, mating type α , MAT α) were used for the incorporation of light chain diversities. Both libraries yielded about $1-2 \times 10^9$ clones after electroporation. Interestingly, the transformation procedure in this approach is facilitated with a linearized DNA for both, the PCR insert as well as the digested plasmid backbone. This is in contrast to the GGC-approach where a circular plasmid is utilized. Still, both approaches deliver library or sub-library sizes in the same range, supporting the notion that gap repair cloning is very efficient for library construction. Subsequently, YM was applied to generate Fab libraries comprising combined heavy and light chain diversities. This resulted into a calculated library size of about 2.2×10^9 independent clones. It should be noted that in the YM approach a simple analysis of heavy and light chain diversities cannot be made, as the final display library is a product of two sub-libraries, which have gone through several rounds of culturing prior to the final library generation. In comparison, the GGC-procedure results in the functional display library after a single step. Therefore, clone numbers obtained from dilution plating might be more comprehensive with respect of diversity in the case of the GGC-approach. In both approaches Fab fragments were displayed on the yeast cell surface *via* fusion to cell wall protein *Aga2p*, which is anchored to the cell wall by

covalent association with Aga1p (Figure 1C). From both libraries approximately 100 clones each were sent out for sequencing to analyze V-family representation. As shown in Figure 2A IgHV families were represented very similarly in both library generation procedures. With regards to IgLV region occurrence, the distribution in both libraries was also comparable (Figure 2B). Whereas families IgLV2-8 and IgVL2-11 seemed to be underrepresented in the GGC-based approach, regions IgLV3-10 as well as IgLV3-12 were found infrequently in YM library, indicating that no profound bias was observed by comparing both approaches. Furthermore, the functionality in both libraries, i.e. functional VH or VL domains without stop codons, frameshifts or deletions was very similar (Supplementary Table 1).

Moreover, the two resulting libraries were selected separately by FACS against recombinant human CEACAM6 protein. In order to analyze the sequence output more comprehensively without the risk of losing binders during library sorting, we decided to apply a low-stringency strategy by applying a fixed antigen concentration of 1 μM for all rounds of sorting. CEACAM6 binding was detected using an Alexa Fluor 647

conjugated anti-Penta-His antibody whereas Fab display was identified simultaneously by application of lambda light chain specific goat F(ab'), R-PE conjugate. Controls, in which cells were stained with secondary detection reagents only were applied to adjust the sorting gates to only consider target positive populations. In the first round of sorting approximately 3×10^5 cells were sorted for both approaches. In subsequent sorting rounds, a minimum cell oversampling by the factor of 10 with respect to the previously sorted cells was ensured. As shown in Figure 3, for both library generation approaches we were able to strongly enrich for antigen-binding populations within three rounds of FACS sorting. Enriched clones were then analyzed by sequencing (Supplementary Figures 1-4) and a clustering strategy was applied in which clones with less than three amino acid exchanges within CDR-H3 belong to the same family. Moreover, at least three sequences must fulfil this criterion to be considered as a cluster. Peculiarly, this revealed that whereas the sequence output of the GGC approach comprised five distinct clusters (Supplementary Figure 1, cluster 1-5), only two of those were present by evaluating the YM approach. Even more interestingly, those two

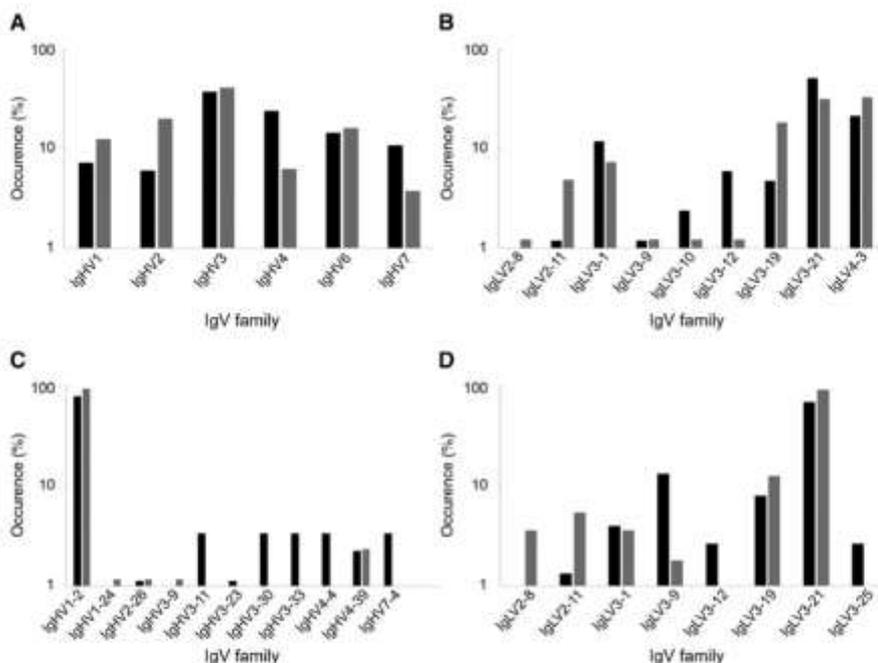

Figure 2: Analysis of IgV-gene occurrence in YSD Fab libraries constructed using GGC (black bars) or YM approach (gray bars). (A) IgHV and (B) IgLV frequencies as found by sequencing after library establishment. (C) IgHV and (D) IgLV occurrence after FACS sorting against recombinant human CEACAM6 protein.

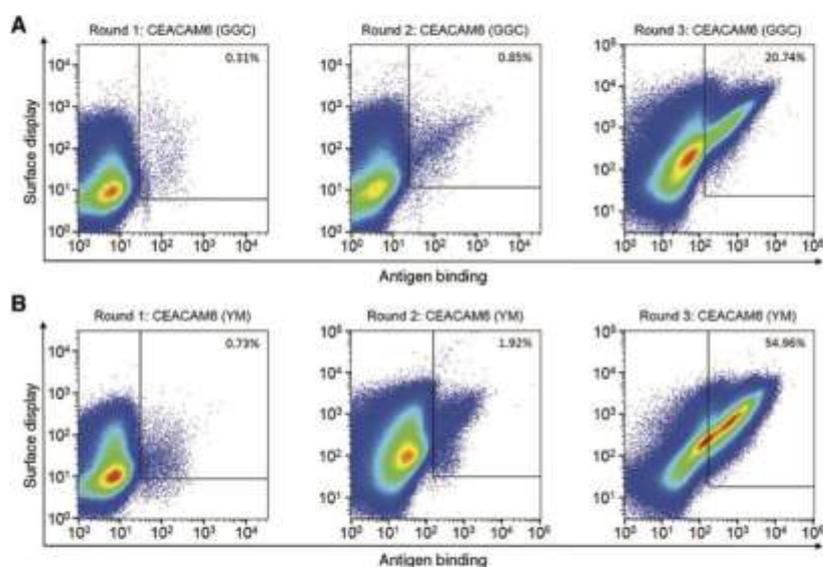

Figure 3: Screening of CEACAM6 YSD Fab immune libraries by FACS. Yeast cells were consecutively incubated with $1 \mu\text{M}$ of His tagged recombinant human CEACAM6 protein followed by secondary labeling with Alexa Fluor 647 conjugated anti-Penta-His antibody and PE conjugated anti-lambda-antibody. (A) Sorting of GGC-based library. (B) Sorting of library based on YM approach.

clusters (Supplementary Figure 3, cluster 2 and 3) were also strongly represented in the GGC approach, indicating a considerable sampling of the immune diversity using this cloning technique for library establishment. These findings were also substantiated by evaluating the V-gene representation (Figure 2C and D). After library sorting, distinct IgHV (IgHV1-2) and IGLV (IGLV3-19 and IGLV3-21) families were represented most prevalent in both approaches, supporting the notion that no substantial liabilities were introduced using the GGC-approach.

From each of the five clusters, one representative clone was reformatted into plasmids enabling the production as full-length IgG moieties in Expi293 cells. After antibody expression and purification using Protein A chromatography, binding kinetics to recombinant human CEACAM6 were investigated via BLI (Table 1, Supplementary Figure 5). Specific antigen binding in the double-digit nanomolar range was observed for the clones from clusters 2 and 3, that were present by analyzing the sequence output in both approaches. Moreover, two out of three clones from the clusters that were only found in the GGC library showed specific binding to CEACAM6 in the picomolar to nanomolar range (clones obtained from clusters 1 and 4), demonstrating clear evidence that in this particular case the GGC approach enabled the isolation of rare but still antigen-specific clones.

Table 1: Kinetic analysis of clones reformatted as IgG.

Clones	Library	Antigen	K_{on} (1/Ms)	K_{off} (1/s)	KD (M)
C1	GGC	CEACAM6	$5.78\text{E}+04$	$1.37\text{E}-03$	$2.37\text{E}-08$
C2	GGC, YM	CEACAM6	$4.60\text{E}+03$	$7.49\text{E}-05$	$1.63\text{E}-08$
C3	GGC, YM	CEACAM6	$4.82\text{E}+03$	$6.26\text{E}-05$	$1.30\text{E}-08$
C4	GGC	CEACAM6	$4.45\text{E}+05$	$1.21\text{E}-04$	$2.72\text{E}-10$
C5	GGC	CEACAM6	–	–	–
E1	Chimeric GGC	EGFR	$1.35\text{E}+05$	$1.36\text{E}-01$	$1.01\text{E}-06$
E2	Chimeric GGC	EGFR	$2.44\text{E}+05$	$1.38\text{E}-03$	$5.65\text{E}-09$
H1	Chimeric GGC	hCG	$1.11\text{E}+05$	$4.28\text{E}-02$	$3.85\text{E}-07$
H2	Chimeric GGC	hCG	$2.03\text{E}+04$	$8.06\text{E}-05$	$3.97\text{E}-09$

Chimeric chicken/human library construction and selection of EGFR- and hCG-specific antibodies

Within this study, we also wanted to figure out whether the GGC approach is applicable in a broader manner. To this end, we aimed at isolating chimeric chicken/human antibodies after avian immunization. Two specimens of *Gallus gallus domesticus* were immunized with EGFR and hCG, respectively. cDNA was prepared using total RNA collected

from spleen tissues with random hexamer primers and subsequently heavy as well as light chain variable regions were amplified in a one-step PCR. Those generated VH and VL modules were grafted onto human CH1 and CL λ regions using GGC. For this, the same entry and destination plasmids as described for the CEACAM6 study were utilized. Consequently, this resulted in two libraries with calculated library sizes of approximately 4×10^8 unique clones, respectively.

The generated libraries were screened separately by FACS for binders targeting recombinant human EGFR and human hCG protein. Target binding was monitored by indirect antigen fluorescence staining and Fab surface display levels were analyzed simultaneously by lambda light chain labeling. As shown in Figure 4, we were able to enrich for antigen-positive populations in two consecutive screening rounds by incubating cells with $1 \mu\text{M}$ or 500 nM antigen, for EGFR and hCG, respectively. Also, no binding against secondary detection reagents could be observed (data not shown). Flow cytometry analysis after library sorting revealed for both screening campaigns almost quantitative antigen binding populations with strong correlation between antigen binding and Fab display

(Supplementary Figure 6). Sequence analysis of the enriched cells showed a very diverse output for heavy and light chain variable domains, respectively (Supplementary Figures 7–10). Notwithstanding, specific CDR3 sequence patterns were highly enriched in both domains. From each library two of the most abundant clones based on region CDR-H3 were reformatted into chimeric chicken/human IgGs, expressed in Expi293 cells and purified *via* Protein A chromatography. Binding kinetics were measured using BLI. All the clones showed specific binding towards their cognate antigen in the low nanomolar to micromolar range (Table 1, Supplementary Figure 5).

Discussion

Yeast surface display, as pioneered by Boder and Wittrup in 1997, emerged as a powerful platform technology for antibody engineering purposes (Colby et al., 2004; Cherf and Cochran, 2015; Grzeschik et al., 2017; Schröter et al., 2018). One benefit of YSD relies in its compatibility with FACS sorting, enabling real-time and on-line analysis of individual library candidates and consequently a fine discrimination of variants comprising desired prescribed properties. Moreover, complex proteins like antibodies are believed to be more properly folded due to the presence of sophisticated quality control machineries in the host *S. cerevisiae* (Doerner et al., 2014). Regarding antibody formats, multiple constructs can be displayed on the surface of the yeast, e.g. scFvs, Fab fragments or single chain Fabs (Boder and Wittrup, 1997; Weaver-Feldhaus et al., 2004; Walker et al., 2009). It was recently shown that functional antibodies are most efficiently displayed in the Fab format (Sivelle et al., 2018). Such Fab antibody libraries are typically constructed in a three-step process consisting of individual heavy and light chain sub-library generation in haploid yeast strains with opposite mating types followed by YM into diploid cells (Weaver-Feldhaus et al., 2004). Besides being very efficient for library creation and sampling (Schröter et al., 2015; Krahl et al., 2017), this technique seems to be laborious and time-consuming. We recently presented an alternative strategy for the construction of Fab antibody YSD libraries using GGC (Rosowski et al., 2018). The charm of this cloning technique relies on the utilization of type II restriction enzymes cutting outside of their respective recognition sequence. By carefully designing restriction site overhangs, i.e. signature sequences, directional one-step cloning is amenable with elimination of the recognition sites during the reaction (Engler et al., 2008). It was shown

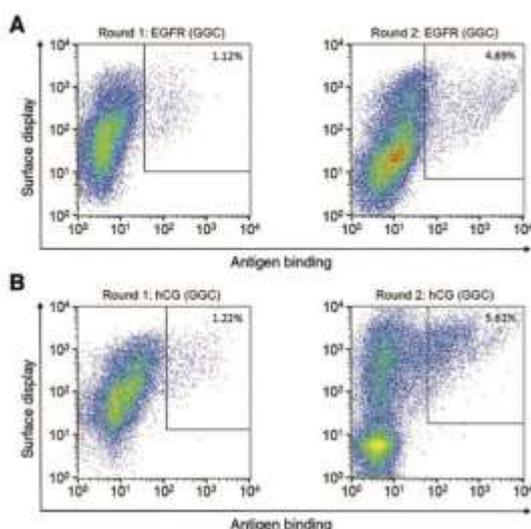

Figure 4: Screening of chimeric chicken/human YSD Fab immune libraries by FACS.

Antigen binding was monitored by indirect antigen fluorescence staining and Fab surface display levels were analyzed simultaneously by lambda light chain labeling. (A) Sorting of recombinant human EGFR GGC-based library using an antigen concentration of $1 \mu\text{M}$. (B) Sorting of recombinant hCG GGC-based library with $0.5 \mu\text{M}$ target protein.

that this cloning principle is also applicable to generate and screen phage display libraries (Nelson and Valadon, 2017; Romão et al., 2018). In our previous work, we used GGC to generate antigen-specific antibodies from heavy chain repertoires only after immunization. For this, the heavy chain repertoire was paired with a fixed light chain and common light chain antibodies were readily isolated. Albeit proven to be a valid tool in this study, the generation of antibodies from both, heavy as well as light chain diversities is more sophisticated. In the present investigations we aimed at more thoroughly comparing the library construction process and selection output of a GGC-based library with that of the conventional three-step process involving YM. To this end, OmniRats were immunized with recombinant human CEACAM6 protein and libraries were constructed using both approaches. Calculated library sizes as well as IgV gene analysis demonstrated a similar quality for both individual approaches and library sorting by FACS enabled the strong enrichment of antigen binding populations. Surprisingly, sequencing of enriched antigen binding populations revealed a broader diversity using the GGC technique. Essentially, three additional sequence clusters were identified in this library and by reformatting and soluble expression of respective cluster representatives we could show that two out of those three clusters comprised additional functional, i.e. target-specific antibodies. However, we cannot exclude that those additional clusters were also present in the YM library and presumably those clones could be identified by more comprehensive sequencing such as next-generation sequencing (Friedensohn et al., 2018). Nevertheless, these findings are indicating that YSD libraries with adequate qualities can be generated by GGC, requiring significantly less hands-on-time compared to conventional methods for Fab library generation.

Nelson and Valadon described in their work BsaI restriction sites being present in a significant fraction of human IgV gene segments (Nelson and Valadon, 2017). With respect to library construction, this has also been described for standard type II restriction enzymes. For example, SpeI restriction sites, an enzyme often used for cloning of antibody genes into phage display plasmids are also found in notable amounts in human IGHV sets. Moreover, commonly used type II enzyme restriction sites such as SacI and XbaI are frequently found in murine antibody light chain variable regions (Barbas et al., 1991; Nelson and Valadon, 2017). Within our study we utilized BsaI for Fab fragment cloning. Interestingly, after library establishment, in approximately 22% of analyzed sequences BsaI sites were still present, even though during GGC the final reaction step comprised an elongated digestion

in order to digest remaining destination plasmid for the sake of library quality. Consequently, it is tempting to speculate that in *S. cerevisiae* DNA repair ligases of the non-homologous DNA end joining pathway facilitate the rescue of potential library candidates comprising BsaI sites (Wilson et al., 1997; Dudášová et al., 2004). Nonetheless, it remains elusive in a broader sense how GGC, i.e. the presence of type II restriction sites in immunoglobulin variable gene segments affects the gene usage of generated libraries. Hence, it will be interesting to investigate more meticulously the YSD library construction process as well as resulting biases using different type II restriction enzymes by next-generation sequencing.

Within this work, we also demonstrated that chimeric chicken/human antibodies can be isolated by YSD in combination with GGC after avian immunization. Chicken antibodies are of interest for biotechnological and biomedical applications. Due to their phylogenetic separation to mammals, human proteins are very often immunogenic to chickens, enabling the generation of antibody repertoires with a broader epitope coverage (Abdiche et al., 2016). Consequently, immune responses can be raised against conserved human proteins that are not immunogenic to mice (Ching et al., 2018). After immunization of two specimens with recombinant human EGFR and hCG, two GGC-based YSD libraries were constructed. Chicken heavy as well as light chain variable domain repertoires were grafted onto human constant domains CH1 and CL λ . Within two rounds of library sorting, we highly enriched antigen binding populations for both antigens, respectively. After sequence analysis we still obtained a large diversity in both libraries. Soluble expression of highly abundant clones in a chimeric chicken/human IgG format revealed high affinities for their cognate antigens, showing clear evidence that GGC is a valid method to generate YSD libraries with adequate qualities in the context of antibody discovery and engineering.

Materials and methods

Immunization of transgenic rats and wild-type chicken

OmniRats[®] (Osborn et al., 2013), transgenic for human antibody variable regions, were immunized by genetic immunization using vaccination vectors encoding for CEACAM6 (R&D Systems, Minneapolis, MN, USA) at Aldevron (Freiburg, Germany), as previously described elsewhere (Krah et al., 2017).

Additionally, two chickens (*G. gallus domesticus*) were immunized with protein antigens. One chicken was immunized with human EGFR (extracellular domain, produced and purified in-house) and another specimen with a cocktail of EGFR and hCG (BBI Solutions,

Cardiff, UK). Immunizations were performed at Davids Biotechnologie (Regensburg, Germany). In brief, two adult laying hens were immunized by intramuscularly injection of 150 µg of the respective antigens using AddaVax (InvivoGen, San Diego, CA, USA) as vaccine adjuvant. After initial injection, the birds received boosters after 2, 4, 5 and 8 weeks. After 9 weeks both animals were sacrificed followed by isolation of total splenic RNA using TriFast reagent (VWR, Radnor, PA, USA), as described elsewhere (Grzeschik et al., 2018).

All experimental procedures and animal care were in accordance with EU animal welfare protection laws and regulations.

Plasmids

Plasmids for GGC were designed in-house and synthesized at GeneArt (Thermo Fisher Scientific, Waltham, MA, USA). Genetic elements were deduced from pYD1 plasmid backbone (Yeast Display Vector Kit, version D, #V835-01, Thermo Fisher Scientific) as well as pESC vector series (Agilent, Santa Clara, CA, USA). The entry plasmid (pEntry) was designed with a kanamycin resistance gene, whereas the destination vector contained an ampicillin resistance cassette as well as a tryptophan selection marker for selection in yeast (Rosowski et al., 2018). Essential elements are given in Figure 1B.

Vectors used for the YM approach were also based on the pYD1 plasmid backbone. The heavy chain plasmid contained a tryptophan auxotrophic marker and an ampicillin resistance marker (Schröter et al., 2015; Krab et al., 2017). The light chain plasmid comprised leucine marker and kanamycin resistance genes. Moreover, the heavy chain plasmid encoded for the AGA2 signal peptide, followed by the antibody VH region genetically fused to the CH1 region of IgG1, which allowed surface presentation of a VH-CH1-GS/Linker-Aga2p fusion protein. The light chain plasmid encoded for the α MFpp8 signal sequence (Rakestraw et al., 2009) for soluble secretion, followed by the sequence for the constant lambda region. Expression of antibody heavy and light chain genes was under control of the galactose inducible promoter (*GAL1*).

Yeast strains and media

For GGC-derived yeast surface display, *S. cerevisiae* strain EBY100 (*MATa URA3-52 trp1 leu2Δ1 his3Δ200 pep4::HIS3 prb1Δ1.6R can1 GAL (pIU2II:URA3)*) was employed (Thermo Fisher Scientific). This strain was also utilized for YM heavy chain sub-library construction. In addition, for light chain sub-library construction (YM) *S. cerevisiae* strain BJ5464 (*MATa URA3-52 trp1 leu2Δ1his3Δ200 pep4::HIS3 prb1Δ1.6R can1 GAL*) (American Type Culture Collection, Manassas, VA, USA) was used. Initially, strains were cultivated in YPD medium composed of 20 g/l peptone (Merck KGaA, Darmstadt, Germany), 20 g/l dextrose (Merck KGaA) and 10 g/l yeast extract supplemented with 10 ml/l penstrep (Gibco, Thermo Fisher Scientific). EBY100 cells harboring library plasmids (pDest) after GGC were cultivated in medium using minimal SD-base (Clontech, Mountain View, CA, USA) with commercially available dropout mix (Clontech) composed of all essential amino acids except for tryptophan, according to the manufacturer's instructions, supplemented with 5.4 g/l Na₂HPO₄ (Merck KGaA) and 8.6 g/l NaH₂PO₄·xH₂O (Merck KGaA). For YM-based library generation EBY100 cells were cultivated accordingly. BJ5464 cells were cultivated using a leucine dropout mix (Clontech).

After YM, diploid yeast cells were cultivated in leucine and tryptophane double dropout mix (Clontech). For induction of antibody gene expression, cells were transferred into respective SG dropout medium wherein glucose was replaced by galactose containing SG-base (Clontech). Additionally, 10% (w/v) polyethylene glycol 8000 (PEG8000, Sigma Aldrich, St. Louis, USA) was incorporated. Furthermore, minimal Synthetic defined (SD) agar base (Clontech) supplemented with respective dropout mixes was used for preparation of agar plates.

Library construction

Total RNA was extracted from 1×10^7 lymph node cells of immunized OmniRats[®] using the RNeasy MiniKit (Qiagen, Venlo, Netherlands) according to the manufacturer's protocol. For cDNA synthesis from both, OmniRat[®] and chicken RNA, 50 µl RNA extract, 20 µl RT-buffer, 40 µl 25 mM MgCl₂, 20 µl 0.1 M DTT, 10 µl RNase Out and the 10 µl Superscript III reverse transcriptase (SuperScript III First-Strand Kit, Thermo Fisher Scientific) was used as well as random hexamer primers (Eurofins Scientific, Luxemburg) (Figure 1A). The reaction was treated as follows: 10 min at 25°C, 50 min at 50°C followed by heat inactivation for 5 min at 85°C. Afterwards, 1 µl RNase H (Thermo Fisher Scientific) was added followed by an incubation step at 37°C for 20 min.

Human heavy and light chain antibody variable regions from OmniRats[®] were amplified from cDNA in two consecutive PCR reactions for both approaches, respectively. First PCR was executed including 12 reactions for VH and 10 reactions for VL λ with 5 µl cDNA in a final volume of 50 µl using a Q5 High-Fidelity 2 \times Master Mix (New England Biolabs, Ipswich, MA, USA) and unique forward primers annealing to germline leader sequences and one reverse primer annealing to rat CH1 or CL λ . PCRs were performed at 95°C for 120 s, 30 cycles of 95°C for 15 s, 58°C for 30 s and 72°C for 90 s. The Wizard[®] SV Gel and PCR Clean-up System (Promega, Madison, WI, USA) was used for the purification of the PCR products, followed by equimolar pooling of the samples. With respect to the GGC-approach, in the second PCR, human VH and VL λ domains were amplified with primers incorporating BsaI recognition sequences for subsequent cloning. Reaction conditions were as follows: 98°C for 30 s, 15 cycles of 98°C for 10 s, 55°C for 10 s and 72°C for 30 s followed by 72°C for 120 s. In contrast, the second PCR for the YM-method was performed to amplify VH and VL λ domains with overlaps to their respective destination plasmids. Reaction conditions were: 98°C for 30 s, 30 cycles of 98°C for 10 s, 58°C for 20 s and 72°C for 45 s followed by 72°C for 120 s. The second PCRs for both approaches were performed with distinct primer set according to Saulquin et al. and Hust and co-workers (Kügler et al., 2015; Ouisse et al., 2017). Primer sequences are given in Supplementary Table 2. Nine forward and one reverse primer for VH regions as well as 11 forward and two reverse primers for VL λ regions were used to amplify antibody variable regions, respectively. PCR products were purified via the Wizard[®] SV Gel and PCR Clean-up System (Promega) and pooled in an equimolar ratio.

For chimeric chicken/human Fab library generation, for each animal VH and VL repertoires were amplified in one PCR reaction, respectively. For each reaction, 5 µl cDNA was utilized in a final volume of 50 µl using Taq polymerase (New England Biolabs) as well as primer sets given in Supplementary Table 2. Reaction conditions were as follows: 95°C for 30 s, 30 cycles of 20 s at 95°C, 30 s at 55°C and 30 s at 68°C, followed by 68°C for 5 min. After PCR purification

via the Wizard® SV Gel and PCR Clean-up System (Promega) samples were pooled for subsequent cloning.

Human as well as chicken antibody variable regions were incorporated simultaneously into a single destination vector for the GGC approach (Krah et al., 2018). Reactions were executed in a final volume of 100 µl using 1 µg of destination vector (Figure 1), 1.4 µg entry vector and approx. 160 ng of pooled VH PCR product, approx. 160 ng pooled VL product as well as 200 U BsaI (New England Biolabs), 800 U T4 DNA ligase (New England Biolabs) and 10 µl 10 × T4 Ligase buffer (New England Biolabs). Reaction conditions were 30 cycles of 1 min at 37°C, 1 min at 16°C followed by 5 min at 55°C. After cloning, six reactions were pooled, purified using the Wizard® SV Gel and PCR Clean-up System (Promega) and eluted in a final volume of 30 µl which were subsequently used for one electroporation reaction into EBY100 as previously described by Benatuil et al. (Benatuil et al., 2010). Ten transformation reactions were performed for library establishment. Library sizes were calculated by dilution plating.

To accomplish library generation via homologous recombination (YM), the destination vectors were linearized with restriction enzymes BamHI (New England Biolabs) and NotI (New England Biolabs) for VL λ or restriction enzymes EcoRI (New England Biolabs) and NotI (New England Biolabs) for the antibody heavy chain. Transformation was performed using 4 µg digested destination vector as well as 12 µg purified PCR product within every transformation reaction according to Benatuil et al. (Benatuil et al., 2010). Ten reactions were performed for the generation of either antibody heavy chain library in EBY100 or antibody light chain library in BJ5464 cells. Library sizes were calculated from serial dilution plating of transformed cells. YM was applied to combine the generated diversities, as described by Weaver-Feldhaus et al. (Weaver-Feldhaus et al., 2004). The haploid cells harboring either antibody heavy or light chain diversity were grown in SD media, lacking tryptophan or leucine, at 30°C and 200 rpm for 24 h. Thereon, cells were pooled and incubated on YPD agar plates at 30°C for 24 h. After this incubation, cells were washed from the plates and used for the inoculation of SD-Trp-Leu double dropout medium. Library sizes were calculated by serial dilution plating on SD-Trp-Leu plates.

Library sorting

Recombinant human His-tagged CEACAM6 extracellular domain as well as Fc-tagged EGFR was purchased from R&D systems. hCG was purchased from BBI Solutions. Recombinant human his-tagged EGFR was produced in-house.

For library sorting, respective library cells were grown overnight in SD medium with adequate dropout mixes at 30°C and 200 rpm. Afterwards, cells were transferred to SG medium with appropriate dropout mix at 10⁷ cells/ml followed by incubation at 20°C for 2 days. Antigen staining was performed either by utilizing biotinylated hCG employing EZ-Link Sulfo-NHS-LC-Biotin (Thermo Fisher Scientific) combined with Streptavidin conjugated to APC or PE (Alfymetrix eBioscience, Thermo Fisher Scientific), or Penta-His Alexa Fluor 647 Conjugate antibody (Qiagen, diluted 1:20) for his-tagged EGFR and his-tagged CEACAM6 or anti-Human IgG Fc PE conjugate (SouthernBiotech, Birmingham, AL, USA) for Fc-tagged EGFR. Fab expression was monitored by incubation with light chain specific goat F(ab')₂ anti-human lambda R-phycoerythrin (R-PE) or Alexa Fluor 647 conjugate (SouthernBiotech, diluted 1:20).

Labeling of cells for FACS analysis or sorting was conducted by two consecutive washing steps of library candidates with PBS (Sigma Aldrich) followed by incubation with the respective antigen at a concentration of 1 µM. After incubation on ice for approx. 30 min an additional washing step was performed, followed by staining with secondary labeling reagents as described already. Finally, cells were washed with PBS (Sigma Aldrich). FACS-sorting rounds were either performed on a Sony SH800 cell sorter (Sony Biotechnology, San Jose, CA, USA), a MoFlo Legacy device (Beckman Coulter, Indianapolis, IN, USA) or on a BD Influx™ cell sorter (BD, San Jose, CA, USA).

Expression and purification of isolated library candidates

Human as well as chicken VH and VL regions were cloned into pTT5 for full-length IgG production (GeneArt/Thermo Fisher Scientific). For this, Expi293 cells were transiently transfected with expression vectors according to the manufacturer's instructions (Thermo Fisher Scientific). Five days post transfection, antibody-containing supernatants were harvested by centrifugation and purified via MabSelect antibody purification chromatography resin (GE Healthcare, Chicago, IL, USA). Finally, the buffer was exchanged to PBS (Sigma Aldrich) pH 6.8 using Amicon Ultra-4 Centrifugal Filters (EMD Millipore, Burlington, VT, USA).

Biolayer interferometry (BLI)

The Octet RED96 system (ForteBio, Pall Life Science, Fremont, CA, USA) was employed for binding kinetic measurements. All steps were performed in a final volume of 200 µl at 30°C and 1000 rpm agitation. Antibodies were loaded on anti-human Fc biosensors (ForteBio) at 5 µg/ml in PBS (Sigma Aldrich) for 300 s. Afterwards, tips were transferred to kinetics buffer [KB; PBS with 0.1% Tween-20 (Merck KGaA) and 1% bovine serum albumin, BSA (Merck KGaA)] for 60 s for sensor rinsing. Association to CEACAM6 (R&D Systems), EGFR (in-house) or hCG (BBI Solutions) (varying concentrations ranging from a minimum of 1.6 nM to a maximum 400 nM in KB) was measured for 300 s followed by dissociation for 600 s (in KB). In each experiment, one negative control was measured, wherein the captured antibody was incubated with KB instead of antigen. Data fitting and analysis was performed with ForteBio data analysis software using a 1:1 binding model after Savitzky-Golay filtering.

Abstract

In this work we present a one-step cloning approach for the establishment of antibody phage display libraries relying on type II restriction enzymes. We show that single chain variable fragment (scFv) libraries with adequate qualities can readily be cloned in a 'scar-less' manner and that the isolation of antigen-specific antibodies from immunized chickens is feasible within three selection rounds. Moreover, we demonstrate the general applicability of this method by rapidly constructing and panning VHH single domain antibody phage display libraries from immunized Llama repertoires.

Keywords Phage display · Golden gate cloning · Type II enzyme · Antibody · scFv · VHH · Single domain antibody

Abbreviations

BLI	Bio-layer interferometry
BSA	Bovine serum albumin
CDR	Complementarity-determining region
ECD	Extracellular domain
EGFR	Epidermal Growth Factor Receptor
ELISA	Enzyme-linked immunosorbent assay
Fab	Antigen-binding fragment
GGC	Golden Gate Cloning
IPTG	Isopropyl-beta-D-thiogalactopyranoside

MTP	Microtiter plate
PBS	Phosphate-buffered saline
RT	Room temperature
ScFv	Single chain variable fragment
TMB	3,3',5,5'-Tetramethylbenzidine
VH	Variable domain of the heavy chain
VHH	Variable domain of the heavy chain of a heavy chain only antibody
VL	Variable domain of the light chain

Background

Monoclonal antibodies emerged as the most important class of biologics on the therapeutic market. The simple fact that over 80 therapeutics have been granted marketing approval as well as that more than 570 antibody-derived candidates are currently being investigated in clinical trials is corroborating their therapeutic and economical potential [1]. The most prominent approach for the generation of antigen-specific antibodies relies on the combination of animal immunization with hybridoma technology, as pioneered by Köhler and Milstein [2]. With the advent of transgenic animals, e.g., rats or mice endowed with partially human antibody gene repertoires [3–7], fully human antibodies can be isolated in this manner. Alternatively, in vitro selection technologies such as phage display, yeast surface display, or ribosomal display enable the isolation of antigen-specific entities from naïve, synthetic as well as immunized repertoires

[8–12]. Here, the key feature that enables the identification of desired candidates from antibody libraries is the linkage between the antibody variant to its coding genetic information. In this respect, phage display is the most established as well as most widely used platform technology. In 2016, six phage-derived antibodies, among them also the best-selling drug Adalimumab (Humira®) [13], were approved for therapy and several further were tested in clinical trials. Only three years later, already 12 antibodies discovered via the phage display platform have reached approval.

In the commonly applied phagemid format [14], the expression of the antibody fragment as fusion with phage envelope protein pIII is uncoupled from phage protein production and phage replication. A morphogenic signal is added for packaging as well as for phage replication. Correct phage assembly thus requires co-expression of other phage proteins, as provided by helper phage [14]. Phage display allows for the generation of huge antibody libraries in different formats such as scFv, Fab as well as single antibody domains [15–19]. However, cloning of libraries comprising heavy and light chain diversities is a tedious and laborious process, for instance, as it requires sequential cloning of the light and heavy chain repertoire into the phagemid [20]. We have previously shown that the process of yeast surface display library generation can be streamlined significantly [21–23]. Utilization of type II restriction enzymes allowed for efficient one-step cloning of heavy as well as light chain diversities into a single Fab display plasmid in a directional manner as well as the isolation of high-affinity antibodies. Similarly, it was demonstrated by Nelson and Valadon that this cloning principle, referred to as Golden Gate Cloning (GGC), is also valid for the construction of phage display Fab libraries [24].

In this present work, we set out to broaden the applicability of GGC for library establishment in the context of phage display by the facile generation of phage display chicken (*Gallus gallus domesticus*) scFv immune libraries as well as camelid (*Lama glama*) single domain VHH immune libraries. To this end, we analyzed the respective antibody germline repertoires for type II restriction enzymes having a minimal or neglectable frequency of recognition sites in antibody variable domain genes. Likewise, PCR-amplified VH-, VL-, and VHH-repertoires, respectively, were scrutinized in this manner, enabling the identification of optimal enzymes for library establishment with minimal restriction enzyme-based bias. A cloning strategy was designed, allowing for one-step library generation (Fig. 1, Fig. S1). Libraries with a high level of insert correctness could readily be constructed using either splenocytes from chicken or PBMCs from llamas immunized with human EGFR antigen (extracellular domain) as starting material, an important target in cancer therapy. Panning of libraries enabled the selection of antigen-specific antibodies with high affinities

ultimately giving clear evidence that GGC is a versatile tool for phage display-derived library construction and antibody hit discovery.

Methods

Animal Immunization

One chicken (*Gallus gallus domesticus*) was immunized with recombinant human EGFR (extracellular domain containing C-terminal hexahistidine-tag, produced, and purified in-house) as described by Grzeschik and colleagues at Davids Biotechnologie (Regensburg, Germany) [25]. Immunization was performed using 150 µg of antigen combined with AddaVax (InvivoGen) adjuvant. After initial administration, the chicken received boosts after 2, 4, 5, and 8 weeks. After 9 weeks, the animal was sacrificed and splenic RNA was isolated. All experimental procedures and animal care were in accordance with local animal welfare protection laws and regulations.

Moreover, two approximately five-year-old llamas (*Lama glama*) were immunized with recombinant human EGFR at preclinics GmbH (Potsdam, Germany). All experimental procedures and animal care were in accordance with local animal welfare protection laws and regulations. In brief, for each immunization 300 µg of EGFR diluted in a volume of 1 ml PBS were emulsified with either 1 ml Complete Freund's Adjuvant (first immunization) or Incomplete Freund's Adjuvant (subsequent immunizations). Injections were administered subcutaneously at three sites. A total of four immunizations were performed over the course of 56 days (day 0, 28, 42, and 56). On day 60, blood (100 ml) was collected and total RNA was extracted. After the study, camelids remained alive. All animals in this study were obtained from the respective service provider.

Plasmids

All plasmids were designed in-house and synthesized at GeneArt (Thermo Fisher Scientific). The plasmid pHAL14 served as template for the Golden Gate Cloning-compatible cloning approach [20]. All destination plasmids were designed to contain an ampicillin resistance cassette, whereas the respective entry plasmids comprised a kanamycin resistance gene.

Library Construction

Following RNA extraction, cDNA was synthesized using 50 µl RNA extract, 10 µl random hexamer primers (50 ng/µl), 10 µl 50 µM dNTPs, 30 µl H₂O, 40 µl 25 mM MgCl₂, 20 µl 10×RT-buffer, 20 µl 0.1 M DTT, 10 µl RNase OUT,

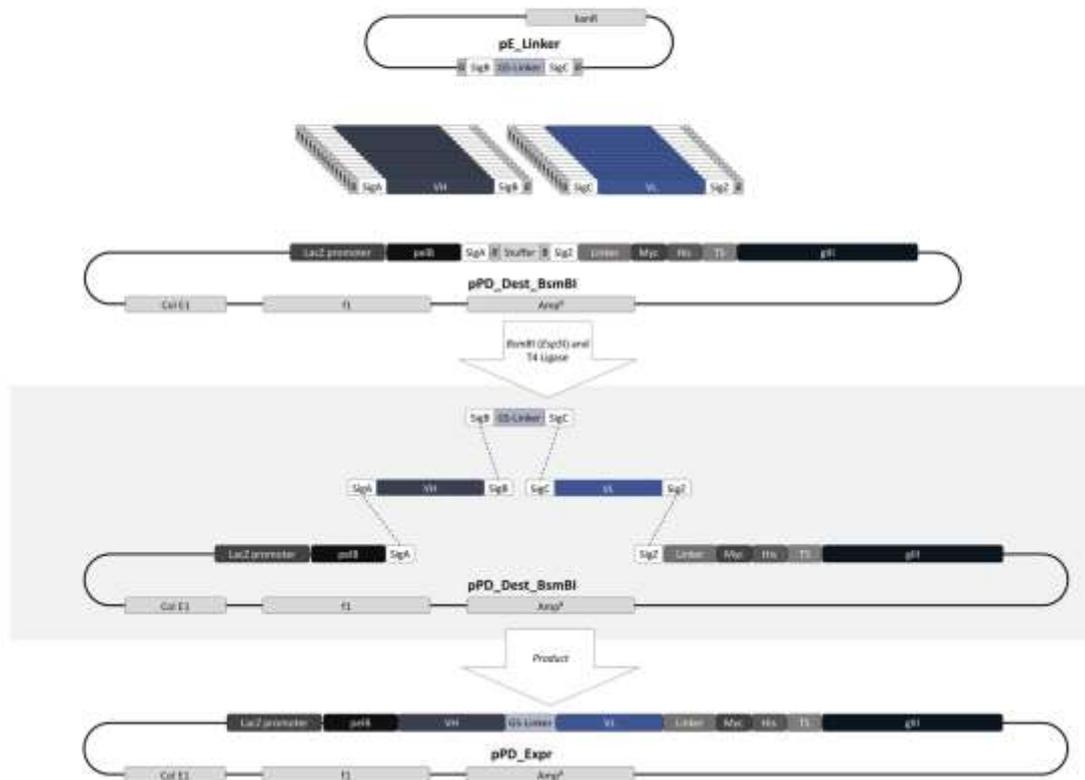

Fig. 1 Schematic overview of the one-step generation process of phage display plasmids for the construction of scFv antibody libraries. The destination plasmid (pPD_Dest_BsmBI) as well as the PCR-amplified VH and VL repertoires contain or are flanked by BsmBI recognition sites in opposite orientations (B: CGTCTCN, B: NGAG ACG). Complementary overhangs i.e., signature sequences (SigX) after Esp3I digestion enable the defined one-pot assembly of the

four-component system during ligation resulting in the final display plasmid (pPD_Expr). ColE1: origin of replication. fl: origin of replication. Amp^r: Ampicillin resistance gene, pelB: leader sequence. Linker: amino acids AAAGS, Myc: c-Myc epitope EQKLISEEDL, His: hexahistidine-tag, TS: trypsin site KDIR, pIII: gene encoding for phage protein pIII. Note that an amber stop codon is introduced between the hexahistidine-tag and the trypsin site

and 10 μ l SuperScript III reverse transcriptase in a volume of 200 μ l (SuperScript III First-Strand Kit, Thermo Fisher Scientific). Reaction conditions were as follows: 5 min at 25 $^{\circ}$ C, 60 min at 50 $^{\circ}$ C followed by 5 min at 85 $^{\circ}$ C. 1 μ l RNase was added followed by incubation for 20 min at 37 $^{\circ}$ C.

For the generation of chicken scFv phage display libraries, heavy and light chain antibody variable regions were amplified from cDNA in PCR reactions using germline specific primers annealing either to chicken heavy or light chain variable region framework 1 (Chicken_BsmBI_VH_up, Chicken_BsmBI_VL_up) and to the chicken framework 4 (Chicken_BsmBI_VH_lo, Chicken_BsmBI_VL_lo). Primer sequences are given in Table S1. The reaction was carried out with 1 μ l cDNA, the corresponding primer pair for VH or VL amplification (each 1 μ l \dot{a} 10 pmol), and Q5 High-Fidelity 2 \times Master Mix (NEB) in a volume of 50 μ l using

the following parameters: 30 s at 98 $^{\circ}$ C, 30 cycles of 30 s at 98 $^{\circ}$ C, 20 s at 60 $^{\circ}$ C, and 30 s at 72 $^{\circ}$ C, followed by a final elongation for 2 min at 72 $^{\circ}$ C. After PCR purification using Wizard[®] SV Gel and PCR Clean-up System (Promega) according to the manufacturer's instructions, amplified VH and VL regions were subjected to GGC employing 1 μ g of destination plasmid pPD_Dest_BsmBI, 1.4 μ g entry plasmid including the linker sequence pE_Link, each 160 ng of VH and VL PCR product together with 400 units Esp3I, 1000 units T4 DNA ligase, and 10 μ l T4 Ligase buffer (all NEB) in a final volume of 100 μ l (Fig. 1). The reaction mixture was incubated for 40 cycles of 1 min at 37 $^{\circ}$ C and 1 min at 16 $^{\circ}$ C followed by a final digestion step for 10 min at 55 $^{\circ}$ C. Following heat inactivation for 20 min at 80 $^{\circ}$ C, an additional restriction step with 5 μ l HindIII (NEB) was performed to digest residual destination plasmid. After

purification of the Golden Gate Cloning reaction by Wizard® SV Gel and PCR Clean-up System (Promega), 30 µl ligation product was mixed with 50 µl of ER2738 electrocompetent *E. coli* cells (Lucigen) on ice. Electroporation was carried out in prechilled 2 mm cuvettes (Genepulser Xcell™) using a MicroPulser electroporator (BioRad) with 2.5 kV. Immediately after pulsing, electroporated cells were diluted in 920 µl SOC medium (Lucigen) with subsequent incubation at 37 °C at 400 rpm for 1 h. The transformation was then plated out on 245 × 245 mm Petri dishes (Thermo Scientific) with 2xYT-GA agar (1.6% (w/v) tryptone, 1% (w/v) yeast extract, 0.5% (w/v) NaCl, 1.5% (w/v) agar-agar, 100 nM glucose, 100 µg/ml ampicillin) and incubated overnight at 37 °C. For evaluating the transformation rate, 10⁻⁶ and 10⁻⁸ dilutions were prepared for each transformation reaction which were analogously plated out and incubated on small Petri dishes (Greiner). The GGC rate was determined either by colony PCR using primers pHAL30_14_fw and pHAL30_14_rev in RedTaq Mix 1.1x (VWR) to check for the correct insert length or by sequencing (Tab. S1). After overnight incubation, transformants were harvested in 25 mL 2xYT medium. 200 µl glycerol (Roth) was added to 800 µl aliquots of bacteria solution which were subsequently stored at -80 °C.

For amplification of llama VHH, germline specific primers annealing to VHH framework 1 (VHH_SapI_up) and to the hinge region (short hinge: VHH_SapI_sh_lo, long hinge: VHH_SapI_lh_lo) was performed as described above (Tab. S1). Subsequently, for GGC 500 ng of purified PCR product was incubated with 1 µg destination plasmid pPD_Dest_SapI with 200 units SapI, 1000 units T4 DNA Ligase, and 10 µl 10×T4 Ligase Buffer (all NEB) using the following reaction parameters: 40 cycles of 1 min at 37 °C and 1 min at 16 °C followed by a final digestion step for 10 min at 65 °C. Plasmid transformation and titration was performed analogously to chicken scFv library construction.

In general, we utilized three different *E. coli* strains for phage display library construction and selections. For library generation, we used ER2738 cells due to very high transformation rates. Because of fast growth rates that allow for performing one round of panning per day, TG1 cells were employed for selections. Finally, XL1 MRF's were used for final infection and plasmid rescue due to adequate plasmid quality after plasmid preparation.

Phage Display Library Packaging

Packaging of each antibody immune library was performed separately by inoculation of the library glycerol stock in 100 ml 2xYT-GA medium (2xTY medium supplemented with 100 µg/ml ampicillin and 100 mM glucose) with a starting OD of ~0.1. The cultures were incubated at 37 °C with 200 rpm until reaching an OD of ~0.5. Then, 5 ml

bacteria culture (~2.5 × 10⁹ cfu) were infected with 5 × 10¹⁰ M13K07 helper phage (NEB) followed by first 30 min incubation at 37 °C without shaking followed by 30 min incubation at 37 °C at 200 rpm. After centrifugation for 10 min at 3220×g at 4 °C, the infected cells were resuspended in 30 ml 2xYT-medium supplemented with 100 µg/ml ampicillin and 50 µg/ml kanamycin. Phages were produced by incubation at 30 °C at 200 rpm overnight. The next day, the cultures were centrifuged for 15 min at 3220×g at 4 °C and the phage containing supernatant was precipitated with 1/5 volume of 20% PEG/2.5 M NaCl solution for 1 h on ice. After centrifugation at 10,000 g for 1 h at 4 °C, the phage pellet was resuspended in 5 ml phage dilution buffer (10 mM Tris, 20 mM NaCl, 2 mM EDTA, pH 7.5). Residual cell debris was removed by further centrifugation at 16,000 g at 4 °C for 15 min and filtrated. After additional precipitation with 1 ml 20% PEG/2.5 M NaCl solution, centrifugation for 45 min at 16,000×g at 4 °C, resuspension in 500 µl phage dilution buffer, and final centrifugation for 1 min at 13,000×g, the phage eluate was stored at 4 °C. Phages were titrated by incubating 10 µl of phage eluate serial dilution (10⁻² to 10⁻⁸) with 1 µl trypsin (Sigma) and 990 µl PBS pH 7.4 for 15 min at 37 °C and adding 10 µl of trypsinated phage reaction to 50 µl ER2738 cells (Lucigen). Cells were plated on 2xYT-GA agar plates overnight at 37 °C and cfu was counted and the number of infecting phage particles was calculated. Display of antibody fragments on phage was evaluated by 4–12% Bis-Tris-SDS-PAGE (Thermo Fisher) and Western Blot which was developed with mouse anti-pIII antibody (1:1000; MobiTec) and peroxidase conjugated goat anti-mouse antibody (1:1000; Jackson Immuno Research, Fig. S2). For each library, 10⁹ of library phage (pfu) were analyzed along with three concentrations of M13K07 helper phage control (10⁷, 10⁸, and 10⁹ pfu, NEB).

Phage Display Selection

In panning round one, approx. 1 × 10¹¹ antibody fragment displaying phages for each library were separately diluted in 2% panning block (2% (w/v) milk powder, 2% (w/v) BSA, 0.05% Tween-20 in PBS pH 7.4), pre-incubated for 1 h in a 96-well microtiter plate well, blocked, and coated with an unrelated protein for negative selection at room temperature (RT). Subsequently, the supernatant was transferred to a well with 250 ng immobilized human EGFR-His (in-house production) for 2 h at RT. Non-bound phages were removed by washing 10-time with PBST (300 µl PBS with 0.05% Tween 20). Target-specific antibody fragment displaying phages were trypsinized for 30 min at 37 °C (10 µg/ml trypsin in 150 µl, Sigma) and were used for infection of 1 ml TG1 cells with OD 0.5 for 30 min without shaking followed by 30 min at 550 rpm at 37 °C. For the output titration, 1 µl of infected TG1 cells was diluted after the first 30 min in 1 ml PBS and

1/10 was plated on 2xYT-GA plates and incubated overnight at 37 °C. To the remaining infected TG1 cells, 3.5 ml 2xYT-GA medium was added for further 30 min incubation. For phage packaging, the TG1 cells were additionally infected with 1×10^{10} M13K07 helper phage (NEB) by 30 min incubation without shaking and 30 min at 550 rpm and 37 °C. After centrifugation at 3220×g for 10 min, the pellet was resuspended in 5 ml 2xYT-AK medium and incubated overnight with 550 rpm at 30 °C. The next day, bacteria were pelleted by centrifugation at 3220×g for 10 min and phage containing supernatant was either stored at 4 °C or used for the subsequent panning rounds. For panning round two and three, the antigen concentration of negative selection target and human EGFR protein was decreased to 100 ng and 50 ng, respectively, and for higher stringency, the number of washing steps was increased to 20-times and 30-times, respectively. For both round two and three, 100 µl phage supernatant from the respective previous round was mixed with 50 µl 2% panning block as input. After the third panning round, trypsinized phages were used to infect 1 ml XL1 MRF⁺ supercompetent cells (Stratagene) for 30 min at 37 °C without shaking. Bacteria were pelleted at 3200 g for 10 min, resuspended in 250 µl 2xYT medium, and plated on 2xYT-A agar plates. The next day, bacteria were harvested from plates in 25 mL 2xYT medium. Bacterial stocks containing 20% (v/v) glycerol were prepared as described above and stored at – 80 °C.

Antibody Production and Screening in Microtiter Plates

Single bacteria clones carrying antibody fragment phagemids were picked from 2xYT-GA agar plates after selection and used for inoculation of 96-well polypropylene MTPs (Greiner) filled with 2xYT-GA medium. After incubation overnight at 37 °C and 700 rpm with 70% humidity, 10 µl of this pre-culture was transferred to 190 µl fresh phosphate-buffered 2xYT-A medium in a new MTP. After 2 h further incubation, 100 µM isopropyl-beta-D-thiogalactopyranoside (IPTG) and 50 mM sucrose were added followed by incubation at 30 °C at 800 rpm overnight. Bacteria were pelleted by centrifugation for 10 min at 3220×g at 4 °C, supernatants were transferred to 384-well MTPs (Greiner) and diluted 1:1 with 2% BSA-PBS.

For the antigen ELISA, 50 ng positive or negative target protein were immobilized on 384-well MTPs (MaxiSorp, Nunc) in PBS pH 7.4 overnight at 4 °C. The next day, wells were washed three times with 100 µl PBST and blocked with 2% BSA-PBST for 1 h at room temperature (RT). After three times of washing with PBST, the expressed antibody fragments were added for an additional 1 h at RT. Antibody fragments bound to the antigen were detected with mouse anti-c-myc antibody followed by goat-anti-mouse IgG secondary antibody

conjugated to peroxidase (Jackson Immuno Research). The colorimetric reaction was performed with the substrate TMB (3,3',5,5'-tetramethylbenzidine) which was stopped with 1 N sulfuric acid after 2 min. Absorbance was measured with a ParadigmTM MTP reader (Beckman Coulter). A clone was declared as hit when absorbance at 450 nm for EGFR-coated well exceeded 1.5, whereas the ELISA signal for the negative control well was lower than 0.8.

Expression and Purification of Isolated Library Candidates

Isolated VHHs were reformatted into pTT5 plasmid as human Fc-fusions. Isolated chicken scFv regions were reformatted as scFv-Fc antibodies (human) [26]. For antibody production, Expi293 cells were transiently transfected with expression vectors (pTT5) according to the manufacturer's instructions (Thermo Fisher Scientific). Supernatants were harvested by centrifugation five days post transfection and purified via MabSelect antibody purification chromatography resin (GE Healthcare). Finally, buffer was exchanged to PBS, pH 6.8, over 24 h at 4 °C using Pur-A-LyzerTM Maxi 3500 Dialysis Kit (Sigma Aldrich/Merck KGaA) followed by a sterile filtration step employing Ultrafree[®]-CL GV 0.22 µm Centrifugal Devices (Merck Millipore).

Bio-layer Interferometry (BLI)

The Octet RED96 system was employed to perform binding kinetic measurements (ForteBio, Pall Life Science). All steps were performed at 30 °C and 1000 rpm agitation. Camelid and chicken-derived antibodies were loaded on anti-human Fc biosensors (AHC) at 5 µg/ml in PBS for 3 min. Subsequently, tips were transferred to kinetics buffer (KB; PBS, 0.1% (v/v) Tween-20 and 1% (w/v) BSA) for 60 s. Association to recombinant human EGFR (concentration range 100–6.25 nM) was measured for 300 s in KB followed by dissociation for 300 s in KB. For each antibody-derivative, a negative control was measured using KB and an unrelated antigen at 100 nM in KB instead of EGFR. Moreover, species cross-reactive binding was assessed at a single concentration of 100 nM recombinant mouse EGFR (ECD, produced in-house). Data fitting and analysis was performed with ForteBio data analysis software 8.0 using a 1:1 binding model after Savitzky–Golay filtering.

Results

Analysis of Type II_s Restriction Sites in Chicken and Camelid Antibody Repertoires

In order to identify suitable type II_s restriction enzymes for Golden Gate Cloning of chicken and camelid antibody

repertoires following immunization, we retrieved IGHV, IgHJ, IgLV, and IgLJ datasets from the IMGT database [27]. Moreover, approximately 100 randomly chosen sequences of PCR-amplified VH and VL genes (*Gallus gallus domesticus*) as well as amplified VHH genes (*Lama glama*) were analyzed in this respect. To this end, we only focused on commonly used type IIIs enzyme BsaI as well as on SapI and BsmBI. The two latter enzymes have been proven to be useful for cloning of antibody repertoires [24]. As presented in Table 1, for BsaI, which is one of the most commonly utilized enzymes for GGC-based approaches, a high frequency of restriction sites in chicken IgLV sets was found. This finding was also confirmed for the PCR-amplified VL repertoire. Similarly, BsaI recognition sites were also found frequently in *Lama glama* IgHV sets as well as PCR-amplified VHH genes. Consequently, this enzyme was excluded for further investigations. On the other hand, chicken as well as llama antibody genes exhibited only very few recognition sites for BsmBI (or Esp3I) and SapI. In case of BsmBI, a restriction site was identified in chicken and camelid IgHJ sets. This has also been reported for human, murine, and rabbit IgHJ genes [24]. Likewise, due to its location near the end of the gene, this site can be readily removed during primer design. Due to a lower presence of BsmBI recognition sites in chicken IgHV sets, this enzyme was selected for cloning of chicken scFv libraries, while SapI was chosen for the construction of VHH single domain antibody libraries.

Design of Phage Display Library Components

For the generation of scFv libraries, we designed a four-component system comprising a destination plasmid, the amplified variable region repertoire of the heavy chain, the amplified variable region repertoire of the light chain as

well as an entry module for the incorporation of a linker of choice (Fig. 1). The destination plasmid was pHAL14-derived [20] and major elements were the LacZ promoter, the pelB leader followed by a stuffer sequence (containing a HindIII restriction site), and the short linker, as well as a myc-tag, a hexahistidine-tag, a trypsin-site, and phage coat protein gene III. Between the his-tag and the trypsin-cleavage site, we incorporated an amber stop codon. Moreover, the stuffer sequence contained BsmBI recognition sites for seamless cloning of ScFv entities. Resulting overhangs, i.e., signature sequences were part of the pelB leader (SigA) or part of the short linker (SigZ). Besides, the plasmid contained an ampicillin resistance gene cassette as well as the ColE1 and the ϕ 1 origins of replication. The entry plasmid contained an 18 amino acid scFv linker, flanked by BsmBI recognition sites. Signature sequences were part of the linker sequence (SigB, SigC). Moreover, this plasmid contained the ColE1 ori for propagation as well as a kanamycin resistance gene. Amplified VH and VL genes were flanked by BsmBI recognition sites as well as corresponding signature sequences (SigA and SigB for VH, SigC and SigZ for VL). Primer sequences for specific chicken antibody variable domain amplification as well as signature sequences can be found in the supplementary material section (Tab. S1, Tab. S2).

For VHH library construction, we designed a two-component system comprising a destination plasmid as well as the amplified VHH repertoire module (Fig. S1). The destination plasmid was designed in a very similar way to the scFv destination module, except for an exchange of the BsmBI recognition sites for SapI recognition sites. Consequently, the amplified VHH repertoire was flanked by SapI sites as well as corresponding signature sequences (SigA, SigZ).

Library Construction, Selection, and Characterization of EGFR-Specific Chicken-Derived ScFv Fragments

It's been known for quite some time, that chicken antibodies can be readily obtained by combining animal immunization with display technologies [28, 29]. To demonstrate that the designed GGC-based approach for library generation allows for the facile isolation of antigen-specific antibodies following avian immunization, we constructed a scFv library of a recombinant human EGFR (extracellular domain)-immunized chicken. To this end, after cDNA synthesis, the heavy chain variable region repertoire as well as the light chain variable region repertoire was amplified using a single PCR step, respectively. Subsequently, both PCR products served as entry modules, together with the entry module comprising the scFv linker and the destination plasmid in a Golden Gate Cloning reaction, yielding the final display vector (Fig. 1, pPD_Expr). Due to its optimal temperature of activity at 37 °C, we decided to utilize the enzyme Esp3I, which is an isoschizomer of BsmBI instead of the latter enzyme that has a temperature optimum of 55 °C. To enhance the efficacy of the reaction i.e., insert rate, a final restriction step with HindIII was performed in order to digest residual destination plasmid. After clean-up, the resulting product was transformed into ER2738 *E. coli* cells in a single electroporation reaction, yielding a small library with a calculated size of 4×10^6 independent clones (Table 2). Library analysis via colony PCR of 48 clones revealed an GGC rate of 92%. Moreover, sequencing of approximately 100 single clones revealed a high correctness of 84% (data not shown). Successful display was verified by Western Blot (Fig. S2). Subsequently, the library was subjected for panning against EGFR. After three rounds of phage display panning with decreasing antigen concentrations (250, 100, 50 ng/well; Tab. S3) and increasing washing cycles, 192 clones were sent out for sequencing (Fig. S3 and Fig. S4), ultimately resulting in 41 unique VHs and 55 unique VLs. To get a more comprehensive view of the diversity of the library output, a clustering strategy was applied in which clones with less than three amino acid exchanges within CDR-H3 belong

to the same family. Moreover, at least three sequences must fulfil this criterion to be considered as cluster. This resulted in the identification of eight sequence clusters.

To add another layer of quality assessment of the library output, we also screened 188 selected library candidates for EGFR binding via ELISA after microtiter expression in *E. coli* (Fig. 2a, Fig. S5) yielding in a hit rate of approximately 50%.

In order to demonstrate, that the isolated chicken-derived entities also bind EGFR when expressed in mammalian expression systems, based on sequence analysis, eight clones were reformatted as scFv-Fc fragments and produced in Expi293 cells (Fig. 3). After purification via Protein A, binding kinetics to recombinant human EGFR were investigated via BLI (Table 3, Fig. S6). All reformatted and expressed scFv fusion protein showed binding against EGFR in the single digit to double digit nanomolar range. Moreover, species cross-reactivity against the murine counterpart, which shows approximately 90% sequence identity to the human protein, was assessed at 100 nM mouse EGFR (ECD). This revealed that six out of eight clones were also able to bind to recombinant murine EGFR in a comparable manner, demonstrating that those molecules might be beneficial as tools in pre-clinical models.

Library Construction, Selection, and Characterization of EGFR-Specific Camelid-Derived VHH Single Domain Antibodies

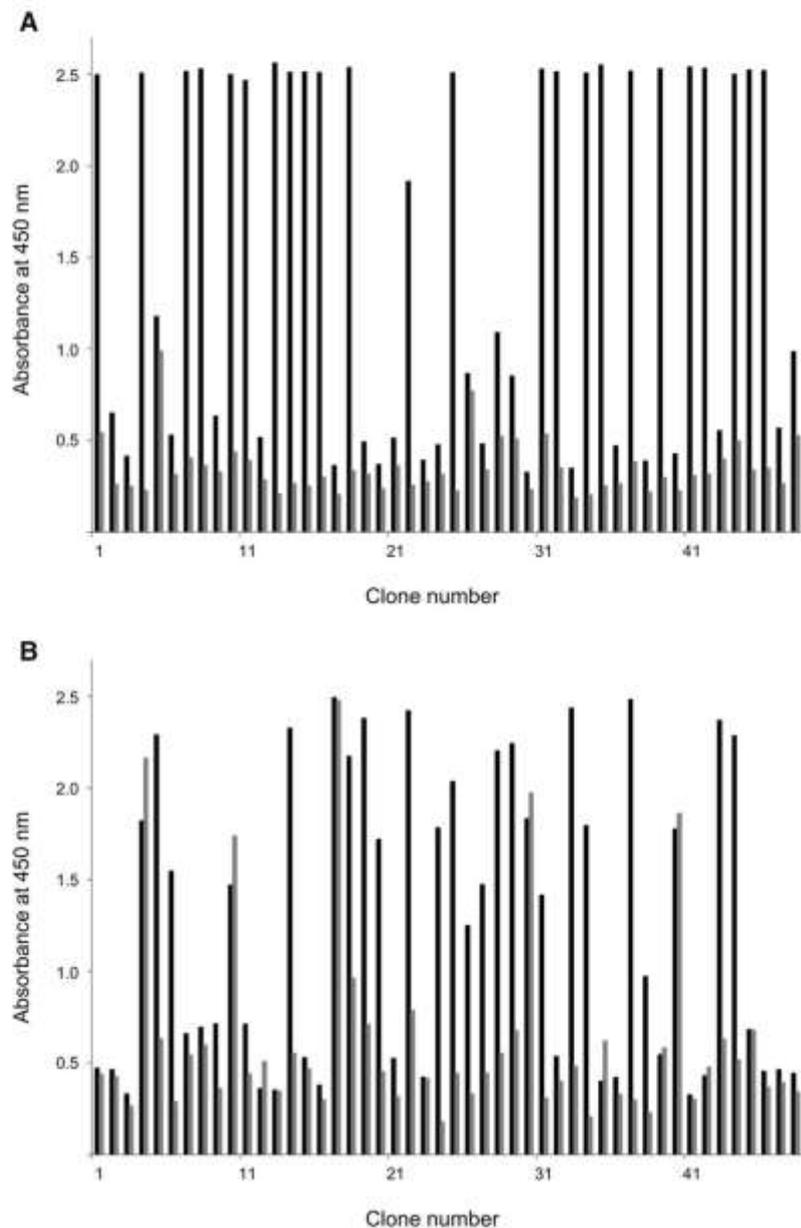

Similar to the generation of the scFv immune library, we aimed at constructing camelid-derived VHH single domain antibody libraries following llama immunization. To this end, we used PBMC-derived cDNA from two EGFR-immunized *Lama glama* as starting material. The forward primer was designed to specifically anneal in framework 1, whereas reverse primers were designed to anneal in the hinge region. Since camelids produce different VHH isotypes comprising short hinge regions and a long hinge regions [30, 31], we designed two different oligonucleotides, respectively (Tab. S1). For each immunized animal, two sub-libraries were constructed, yielding a total number of four VHH phage

Table 2 Analysis of constructed EGFR scFv and VHH libraries

Library	Misc	Library size (per electroporation reaction)	GGC rate (%)	Phage titer (total)
Chicken ScFv	–	4×10^6	92	3.5×10^{12}
Llama 1 VHH	Short hinge	1×10^6	83	4.0×10^{12}
	Long hinge	5×10^6	96	4.5×10^{12}
Llama 2 VHH	Short hinge	4×10^6	83	3.0×10^{12}
	Long hinge	5×10^6	75	3.5×10^{12}

Library sizes as calculated by serial dilution plating are given per electroporation reaction. GGC rates were determined by colony PCR. Phage titer was assessed by serial dilution plating

Fig. 2 ELISA screening after microtiter production of selected library candidates in *E. coli*. **a** Screening outcome of EGFR-immunized avian scFv antibody library after three rounds of selection, **b** Screening outcome of EGFR-immunized llama VHH single domain antibody library after three rounds of panning. A representative block of 48 consecutive clones as assessed by ELISA is shown. Black: ELISA signal against EGFR, gray: Absorbance at 450 nm against unrelated negative control antigen

display immune libraries. Consequently, four GGC reactions were performed in total using the respective PCR product as entry module and the destination plasmid (Fig. S1). For each library, only one electroporation reaction was performed into ER2738 cells, yielding library sizes in the range of 1 to 5×10^6 . GGC rates as determined by colony PCR were in

the range of 75% to 96% (Table 2). All constructed libraries showed display on the surface of phage particles, as demonstrated by Western Blot (Fig. S2). Subsequently, the different VHH libraries were selected against plate-immobilized EGFR in parallel. After three rounds of library panning using step-wise reduced antigen concentrations (Tab. S3), a

H3 is shaded in red, CDR-L3 shown in blue. Alignment was created using MUSCLE Alignment tool within Geneious Prime software (www.geneious.com)

total number of 192 clones (i.e., 48 clones per sub-library) were sent out for sequencing revealing 69 unique sequences (Fig. S7). Moreover, a total number of 752 clones were screened for EGFR binding in an ELISA screening after MTP production, resulting in a hit rate of approximately 20% (Fig. 2b, Fig. S8). Nine clones were reformatted into a VHH-Fc fusion and expressed in Expi293 cells. After purification via protein A, binding kinetics were obtained

using BLI (Table 3, Fig. S6). This revealed binding of six VHH-Fc fusion proteins against recombinant human EGFR with a broad spectrum of affinities, ranging from high-affinity binding (picomolar) to moderate binding in the triple digit nanomolar range. Moreover, three clones also showed species cross-reactive binding against recombinant mouse EGFR similar to the human counterpart.

Table 3 Binding kinetics of selected and recombinantly expressed scFv-Fc and VHH-Fc fragments against rhEGFR as assessed by BLI

Cross-reactive binding against rmEGFR at 100 nM is also indicated

Discussion

Phage display is the most frequently used platform technology for antibody hit discovery and has delivered several therapeutic entities that have been granted marketing approval [13]. It was demonstrated that therapeutic entities can be successfully generated from synthetic or naïve as well as from immunized repertoires [32–36]. Canonical antibodies i.e., antibodies comprising heavy as well as light chain diversities, are typically displayed either as Fab- or scFv fragments on the surface of phage particles [15, 16]. Either way, the construction of such libraries is typically tedious, involving multiple consecutive steps [16, 20]. Our group has recently demonstrated that the construction of antibody Fab libraries for Yeast Surface Display can be significantly simplified by employing a one-step, one-pot type II restriction enzyme-based process referred to as Golden Gate Cloning [21, 22]. Likewise, it was shown by Nelson and Valadon that GGC also enables the facile generation of Fab antibody libraries for phage display [24]. Moreover, the authors elegantly analyzed the occurrence of type II restriction sites in human, mouse as well as rabbit antibody gene repertoires. In this present work, we set out to adapt a similar strategy for the construction of scFv antibody libraries as well as camelid single domain antibody libraries for phage display. To this end, we first analyzed the frequency of three different type II restriction sites in chicken and llama antibody repertoires. Essentially, we focused on BsaI as one of the most commonly used enzymes for GGC approaches as well as on BsmBI and SapI, since those enzymes were found to be suitable for the construction of human, mouse, and rabbit antibody

libraries [24]. Essentially, this revealed optimal enzymes for the construction of chicken scFv as well as camelid VHH single domain libraries. We demonstrate that the GGC approach enables the generation of libraries in the range of 5×10^6 unique clones per electroporation reaction and that the constructed libraries exhibited high functionalities i.e., insert rates. Consequently, libraries with diversities in the range of 10^8 clones can be readily constructed in a convenient way which should be sufficient to adequately sample immune repertoires following immunization. However, for the generation of naïve or synthetic libraries, one typically aims for diversities in the range of 10^{10} – 10^{11} in order to be generally applicable [37]. In this respect, a lot of optimization would be required. Nonetheless, even with the constructed proof-of-concept libraries we were able to select for a diverse panel of antigen-binding antibodies from both, the EGFR-immunized avian scFv as well as from the EGFR-immunized camelid VHH libraries. Recombinantly expressed entities showed a broad spectrum of different affinities against EGFR in the single to double digit nanomolar range for chicken-derived scFv-Fc proteins and triple digit picomolar to triple digit nanomolar range for camelid-derived VHH-Fc fusions.

Conclusion

Besides being the most successfully applied platform technology for the generation of therapeutic antibodies, the construction of phage display library remains challenging and cumbersome. Recently, a significantly simplified process

of library construction was presented by Nelson and Valadon [24]. In their work, the authors describe the generation of phage display Fab libraries using a type II_s restriction enzyme-based process. Herein, we adopted a similar strategy for the establishment of scFv and single domain antibody libraries. We demonstrate that libraries with adequate qualities can be readily cloned using this one-step approach enabling the rapid isolation of antigen-specific antibodies from immunized animals.

Acknowledgements We are grateful to Prof. Harald Kolmar for providing RNA and cDNA from EGFR-immunized chicken.

Author contributions SZ, CS and LP designed the experiments. LP, CB, EC, BV, LT, SB and SK performed in silico analysis and experiments. JK, AF and MH gave scientific advice and guidance on overall strategy. CS, LP and SZ wrote the manuscript.

ABSTRACT

Here, we report the characterization of a VHH-derived IgG-like bi- and trispecific antibody platform that essentially relies on the replacement of the VH and VL regions of a conventional antibody by two independently functioning VHH domains. Consequently, a VHH is engrafted onto constant region CH1 while the other VHH-based paratope is engrafted on the constant region of the light chain, C κ or C λ , resulting in a tetravalent bispecific IgG-like molecule. Combined with a heavy chain heterodimerization technique, this platform allows facile engineering of bi- and trispecific antibodies with flexible valencies. We demonstrate the general applicability of this generic platform approach and elaborate on the limitations of specific formats.

Introduction

During the past decades, monoclonal antibodies emerged as promising treatment options for various diseases. Today, more than 80 entities have been granted marketing approval and over 570 antibody-based therapeutics are currently being evaluated in clinical trials.^{1,2} From a structural perspective, conventional antibodies are large and complex hetero-tetrameric proteins composed of two identical heavy chains as well as two identical light chains, and are monospecific by nature. Consequently, they can only target one antigen. However, diseases are typically complex and originate from multiple different factors or mediators.^{3,4} In order to address diseases more adequately, substantial efforts have been made to engineer antibodies for bispecificity, and a plethora of different formats with different layers of complexity are known today.^{5,6}

In addition to conventional antibodies, sharks and camelids produce antibodies that are composed of heavy chains only. The paratopes of those isotypes consist of a single variable domain that solely facilitate antigen binding and that are referred to as variable domains of New Antigen Receptor (vNARs, in sharks) or variable domains of the heavy chain of a heavy chain only antibody (VHHs, in camelids).^{7,8} Due to their small size, which might be beneficial for tissue penetration⁹ as well as their ease of generation^{10–12} good stability and simple architecture, which allows multiple reformatting options, single-domain antibodies evolved as promising alternatives to conventional antibodies.¹³ While the therapeutic engineering of shark-derived single-domain antibodies is still at a preclinical stage, numerous VHH-derived molecules have progressed into clinical development.¹⁴ Moreover, one VHH-based therapeutic, caplacizumab was approved for the

treatment of patients with acquired thrombotic thrombocytopenic purpura by the US Food and Drug Administration (FDA) in 2019.¹⁵

The general modularity of VHHs enables unprecedented possibilities for the construction of bi- and multispecific antibodies. Consequently, a multitude of VHH-based formats with different valencies as well as specificities have been described in the literature, including multispecific tandem arrangements in a 'beads-on-string' manner, VHH-Fc fusions and VHH-antibody fusions.^{16,17} In 2013, Baty and colleagues described a bispecific VHH-based format that uses the constant domains C κ and CH1 of IgG as natural dimerization domains.¹⁸ In this regard, the authors replaced the variable domain of the heavy chain as well as the variable domain of the light chain by two VHHs, targeting carcinoembryonic antigen and Fc γ RIIIa, respectively. This resulted in an antigen-binding fragment (Fab)-like bispecific molecule eliciting potent tumor lysis by natural killer (NK) cells. More recently, the authors extended the applicability of this format by targeting human epidermal growth factor receptor 2 (HER2)¹⁹ and mesothelin.²⁰

In this study, we set out to investigate whether this Fab-derived bispecific building block can be used to generate a generic IgG-like platform that allows for facile reformatting in bi- and trispecific VHH-based antibodies with flexible valencies (Figure 1(a)). By genetically fusing this Fab-derived bispecific VHH module on an IgG1 Fc backbone, bivalent (for each antigen) bispecific IgG-like antibodies can be obtained (Figure 1(b)). Combining this building block with a heavy chain heterodimerization technique allows facile reformatting into a monovalent bispecific IgG-like entity (Figure 1(c)). To this end, the strand-exchanged engineered domain (SEED)

The model is based on *pdb:5dk3*²¹ and was generated using PyMOL v0.99. (b) Bivalent bispecific VHH-based IgG-like antibody employing an IgG backbone. (c) Utilization of the strand-exchanged engineered domains (SEED) technology enables the generation of monovalent bispecific moieties. (d) Monovalent trispecific VHH-based SEEDbodies can be generated by grafting a third VHH onto the hinge region of the SEED GA chain. (e) Trispecific VHH-based SEEDbody comprising bivalency of the light chain-grafted VHH. (f) Schematic depiction of a one-armed VHH-derived control molecule.

technology was applied.²² This method is based on beta-strand exchanges of IgG and IgA CH3 domains, yielding preferentially heterodimers without impairing Fc-mediated effector functions. This also enables the generation of trispecific moieties with different valencies (Figure 1(d,e)). By characterizing this platform with respect to biophysical and biochemical properties, we show the benefits as well as limitations of the herein described in different formats. Moreover, when substantial paratope-dependent effects (i.e., steric hindrance) arise, we demonstrate that this can be counteracted by simply placing a 10 amino acid flexible linker between the respective VHH domain and the constant domain region of the light chain. Ultimately, we conclude that most of the different formats of the herein presented platform approach seem to be adequate to expand the 'playground' of multispecific VHH-based antibody engineering.

Results

Design of different formats

Within this study, we aimed at developing and characterizing a generic platform approach for the facile generation of IgG-like bi- and trispecific VHH-derived antibodies. Essentially, the platform is based on the replacement of the variable domains of a human antibody by two independent VHH-based paratopes (Figure 1(a)). Consequently, one VHH is grafted onto domain CH1 of IgG1, whereas the second VHH is grafted either on domain C κ or C λ . In order to get a profound understanding of this platform approach, i.e., of the respective formats (Figure 1(b,e)), we decided to use four different VHHs. One VHH was directed against HER2 (sequence derived from WO2016016021). Two paratopes were directed against epidermal growth factor receptor (EGFR), wherein clone 9G8 was

described by Ferguson and coworkers²³ and clone 722C03 was derived from an internal yeast surface display campaign.²⁴ Finally, an NKG2D-targeting VHH sequence was obtained from WO2017081190. Sequences of the respective VHHs can be found in supplementary Figure S1A. Design examples of VHH engraftments on constant antibody regions CH1, Cx, or Cλ are shown in supplementary Figure S1B.

In regard to the different formats, we wanted to include at least some flexibility regarding specificities (bi- and trispecific versions) as well as valencies for a cognate epitope (mono- and bivalent). When the VHH-engrafted Fab is expressed on an IgG backbone for instance (Figure 1(b)), this results in a bispecific IgG-looking molecule, that is tetravalent by design (and bivalent for each antigen). By simply using a heavy chain heterodimerization technique, i.e., SEED technology (Figure 1(c)), one can express one-armed versions of the VHH-based bispecific. This enables bivalency and accordingly monovalent targeting of each epitope. Consequently, this also allows for a very thorough characterization of the platform with respect to functional properties, e.g., simultaneous binding on the protein and cellular level as well as investigations on paratope-dependent effects, i.e., steric hindrance. This monovalent bispecific format (i.e., monovalent for the respective target) can easily be extended into a trispecific format that is monovalent for each antigen by simply placing a third VHH-derived paratope onto the hinge region of the second heavy chain (Figure 1(d)). Finally, by placing two VHH-engrafted Fabs on each heavy chain, the platform also allows trispecific targeting in which the paratope grafted onto the constant region of the light chain is bivalent (Figure 1(e)).

Expression and characterization of monovalent bispecific IgG-like VHH-based antibodies

To gain a thorough understanding of the functionality of each engrafted paratope in this platform approach, we first focused on the generation of monovalent IgG-like VHH-based bispecific antibodies (Figure 1(c)). For heavy chain heterodimerization,

the SEED technology was applied, which is based on beta-strand exchanges of IgG and IgA CH3 domains, resulting in two non-identical heavy chains referred to as AG chain and GA chain. For the SEED GA chain, it is known that homodimers might form, clearly representing a misassembled side product that might affect the analysis of the respective construct in manifold ways, e.g., kinetic measurements and size exclusion profiles. In order to obviate this, the RF mutation was introduced, preventing binding of GA:GA homodimers to protein A.²⁵ Consequently, only AG-GA heterodimers are purified, since AG-AG species typically do not assemble. In this particular monovalent bispecific format, the VHH-based heavy chain of the Fab was expressed on the AG chain, while the GA chain solely comprised the hinge region (one-armed IgG-like VHH-SEED). To allow for direct comparisons to the parental VHHs, i.e., VHHs not engrafted into this bispecific construct, each camelid-derived variable domain was also expressed as one-armed SEED control (Figure 1(f)). To get a more comprehensive view on this format, we produced all four different VHHs in the bispecific monovalent IgG-like scaffold and tried different orientations as well as lambda and kappa backbones for grafting the second paratope onto the constant region of the light chain. The expression of all monovalent bispecific IgG-like VHH-based molecules resulted in fairly equal expression yields compared to one-armed control molecules (Table 1). To be more precise, expression yields as determined after protein A purification were in the triple-digit milligram per liter scale, indicating good expression profiles of all the molecules scrutinized in this particular format. Moreover, thermal stabilities of individual bispecific constructs were very similar to the implemented VHH displaying the lower aggregation onset temperature. Aggregation properties were also in general quite similar to the control molecules as well. Except for one molecule (Table 1, monovalent bispecific entry MoBi12) size exclusion chromatography (SEC) profiles were above 90% target peak. Hence, the results clearly indicate the favorable biophysical properties of the herein described monovalent bispecific IgG-like VHH-based antibody format.

Table 1. Biophysical and biochemical properties of one-armed control molecules and monovalent bispecific series of engineered molecules. Format designs are indicated as well as expression yields post protein A purification, T_{onset} , and size exclusion chromatography target monomer peaks. Affinities as determined by biolayer interferometry are also given.

Next, we aimed at characterizing the biochemical properties. To this end, affinities were determined *via* biolayer interferometry (Table 1). For all different VHH-derived paratopes and all the different orientations as well as kappa and lambda backbones, affinities of the bispecific molecules were similar to the parental molecules. However, as shown in Fig. S2, the total interference pattern shift in the association step of all analyzed monovalent bispecifics was slightly diminished compared to the parental clones. Still, association and dissociation rates were nearly identical, indicating no substantial loss of affinities (Tab. S1). To analyze this in more detail in a cellular context, we focused on molecule MoBi8 (Table 1), which consists of EGFR-specific VHH 9G8 grafted on the AG chain as well as a HER2-specific VHH fused to the constant region of the lambda chain. As shown in Figure 2, both paratopes can independently engage in the cellular binding of target-positive cell lines in a concentration-dependent manner similar to the respective monospecific control molecules (Ctrl1 and Ctrl3), supporting the notion that the functionality of each

VHH is not compromised significantly in this bispecific architecture. Importantly, no binding was observed against the antigen-negative control cell line.

In addition, all bispecific one-armed IgG-like VHH-SEEDs showed simultaneous binding to their antigens on the protein level (Fig. S3). Interestingly, as depicted in Figure 3(a), when grafted onto the kappa constant region, the HER2-specific VHH (Table 1, entry MoBi7) showed compromised HER2-binding compared to the lambda counterpart (Table 1, entry MoBi8), when EGFR-specific VHH clone 9G8 that was fused to the AG heavy chain already bound its antigen, clearly demonstrating paratope-dependent positioning effects in the kappa context. Surprisingly, this phenomenon was neither observed to a significant extent when EGFR-specific clone 722C03 was grafted onto the AG chain nor when the VHH directed against NKG2D (extra-cellular domain (ECD)) with a molecular weight of 18.4 kDa is a much smaller protein compared to EGFR (ECD) with 71.4 kDa. Consequently, it is tempting to speculate that steric

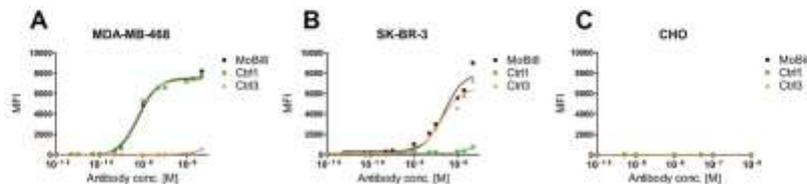

Figure 2. Cellular binding of monovalent bispecific antibody MoBi8 (black) and monospecific control molecules Ctrl1 (green) and Ctrl3 (orange) to EGFR-positive MDA-MB-468 (a) and HER2-positive SK-BR-3 cells (b) as well as to EGFR/HER2-negative CHO cells (c). 1×10^5 target cells were incubated with the respective antibody in varying concentrations.

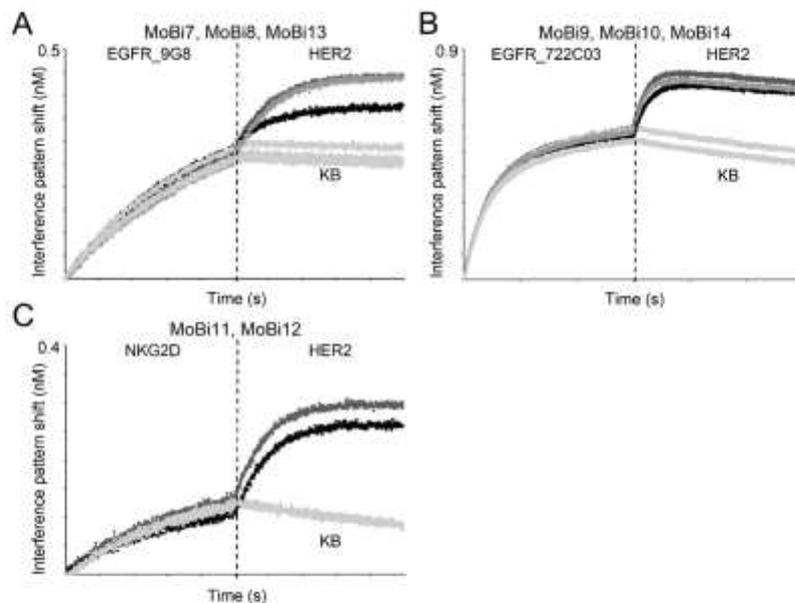

Figure 3. Biolayer interferometry analysis to assess simultaneous binding of one-armed monovalent bispecific molecules. The association of the respective antigen (50 nM) was measured, followed by a second association step using HER2 (50 nM). (a) Association of one armed monovalent bispecific entities MoBi7 (CLx, black), MoBi8 (CLx, dark gray) and MoBi13 (CLx + 10 aa linker, gray) against EGFR and HER2 (or kinetics buffer (KB) as control, light gray). (b) Simultaneous binding of one armed monovalent bispecific molecules MoBi9 (CLx, black), MoBi10 (CL, dark gray) and MoBi14 (CLx + 10 aa linker, gray) against EGFR and HER2 (or KB, light gray). (c) Binding of one armed monovalent bispecific moieties MoBi11 (CLx, black) and MoBi12 (CL, dark gray) against NKG2D and HER2 (or KB, light gray).

hindrance might be the cause for impeded simultaneous binding. In terms of the strikingly different binding behavior of the HER2 paratope in the EGFR context, it is worth noting that both EGFR-specific VHHs address different non-overlapping epitopes (Fig. S4). Therefore, we assume that 9G8 binds an epitope of EGFR in a way that EGFR negatively impacts the accessibility of HER2 to the kappa-engrafted entity. In order to address this more meticulously, we simply placed a 10 amino acid linker between the HER2-specific paratope and the kappa constant region (Fig. S1B, Table 1, entry MoBi13). This restored the binding capacity of the HER2-VHH, clearly corroborating that steric hindrance is the main reason for the positioning effects (Figure 3(a)). We also determined the affinities of all three monovalent bispecifics against HER2, when the inner (AG chain) EGFR-directed VHH 9G8 bound its antigen in saturation (Figure 4). When grafted onto the lambda chain, the overall affinities for HER2 were quite similar, irrespective of the EGFR-specific paratope engaged in antigen-binding or not. Still, even in the lambda context, the total interference pattern shift during association decreased somewhat, indicating also a moderate decline in binding capacity. However, when grafted onto the kappa light chain, not only the total interference pattern shift dropped substantially but also the overall affinities were compromised by a factor of approximately 10 for HER2-binding. This effect could be counteracted in both regards by placing a 10 amino acid linker between the HER2-paratope and the kappa constant region. Interestingly, when the VHH orientation in this format was inverted, i.e., when the HER2-specific paratope was grafted onto the AG chain and EGFR-specific VHH 9G8 was placed onto the light chain, this effect was also observed (Fig. S5), corroborating this paratope-specific positioning effect.

In certain disease settings, a therapeutic (bispecific) antibody must be able to bind to its antigen multiple times throughout its half-life. To investigate whether the architecture of this format permits periodic binding, consecutive association and dissociation cycles were performed for one exemplarily chosen molecule (MoBi8) on the Octet Red system (Figure 5). The bispecific entity showed periodic binding to EGFR as

well as HER2 comparable to the mono-specific controls. Moreover, consecutive association and dissociation against both antigens in an alternating manner was also observed, clearly demonstrating the ability to bind multiple times in a bispecific mode of action.

Furthermore, we set out to investigate if this format also enables simultaneous binding on a cellular level. To this end, the EGFR-positive cell line MDA-MB-468 was labeled with CellTracker™ Deep Red Dye whereas HER2-positive SK-BR-3 cells were labeled with CellTrace™ CFSE. Of note, HER2-positive cell line SK-BR-3 is also slightly EGFR-positive. However, since only one EGFR-paratope was engrafted into this monovalent bispecific format, the entity can either bind one cell type or the other, not both. If a bispecific molecule is able to bind both antigens simultaneously, this will result in antibody-mediated clustering of both cells. Consequently, this can be analyzed by fluorescence-activated cell sorting since cell clustering appears as a double-positive event. As shown in Figure 6, EGFR- and HER2-targeting monovalent bispecific IgG-like VHH-based SEED MoBi8 bound simultaneously to both cell types because clustering was observed in a concentration-dependent manner, whereas no significant increase in double-positive events was detected for EGFR- or HER2-specific one-armed monospecific control molecules (Fig. S6). Importantly, monovalent bispecific IgG-like VHH-based SEED molecules either targeting HER2 and NKG2D or EGFR and NKG2D did not enable the clustering of both cell types, giving clear evidence that the architecture of this platform approach affords the benefit of simultaneous binding also in a cellular context.

Similar to Baty and coworkers,¹⁸⁻²⁰ we set out to demonstrate whether this format bears the potential to be used for effector cell redirection. To this end, a tumor cell killing assay was performed using all four different EGFR (9G8) and NKG2D-specific variants of the MoBi series using peripheral blood mononuclear cell (PBMC)-isolated NK cells as effector cell population (Fig. S7). All EGFR- and NKG2D-targeting monovalent bispecific entities elicited the killing of EGFR-overexpressing A431 cells in a dose-dependent manner,

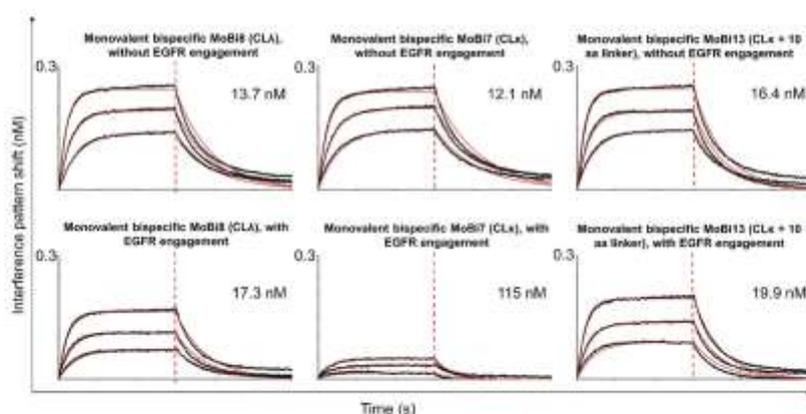

Figure 4. Kinetic measurements of monovalent bispecific VHH-derived IgG-like SEEDbodies MoBi7, MoBi8 and MoBi13 against HER2 in the presence or absence of EGFR binding of the heavy chain-engrafted VHH 9G8 in saturation. After loading and sensor rinsing, a first association step was performed using EGFR in saturating conditions or kinetics buffer (KB). Afterward, kinetics were analyzed against HER2 in the presence or absence of EGFR.

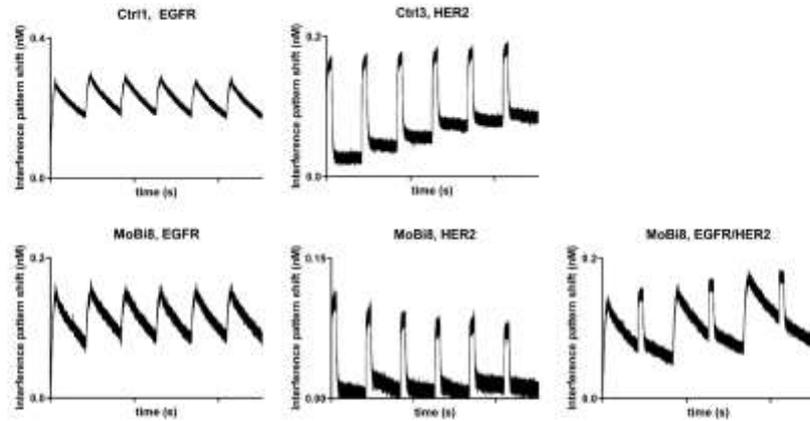

Figure 5. Periodic binding of mono-specific controls Ctrl1 (EGFR) and Ctrl3 (HER2) as well as bispecific MoBi8 (EGFR/HER2) antibody to their corresponding antigens at a concentration of 50 nM. Consecutive association (300 s) and dissociation (30 min) cycles were performed six times in total.

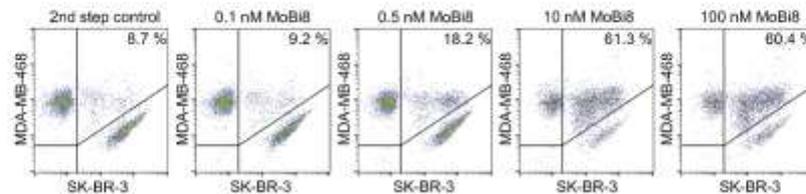

Figure 6. Simultaneous cellular binding analysis of monovalent bispecific antibody MoBi8. Binding to EGFR-positive cell line MDA-MB-468 and HER2-positive cell line SK-BR-3 was assessed by flow cytometric analysis. Of note, MDA MB 468 was labeled with CellTracker™ Deep Red Dye and HER2-positive SK-BR-3 cells were labeled with CellTrace™ CFSE to allow for double-positive fluorescence gating.

whereas no significant tumor cell lysis was observed for unrelated control molecules.

Expression and characterization of bivalent bispecific IgG-like VHH-based antibodies

Bivalent targeting of two different disease mediators might be beneficial for specific therapeutic applications such as cytokine trapping. From a conceptual perspective, the herein characterized monovalent bispecific format can be readily extended into a bivalent counterpart by exchanging the SEED technology for an IgG1 backbone (Figure 1(b)). To get a glimpse of the biochemical and biophysical properties of this format, we expressed nine different bivalent bispecific IgG-like VHH-based antibodies, essentially using all four different paratopes. Moreover, the

kappa as well as the lambda constant regions were taken into consideration for light-chain engraftments. Interestingly, expression yields after protein A chromatography indicated in general good production profiles (Table 2). Some of the molecules, however, were prone to aggregation or showed low molecular weight species as determined by analytical SEC (Fig. S8). In direct comparison to the monovalent counterparts, it is noteworthy that tendencies for aggregation or mis-assembly of the molecule (as indicated by small molecular weight species) were significantly aggravated. In this respect, for one molecule (BiBi4), the target peak declined to only 72%, meaning that substantial efforts in downstream processing would be required in order to consider such a molecule for further development. On the other hand, two molecules exhibited quite decent SEC profiles (BiBi1 and BiBi6). Since some of the molecules with

Table 2. Biophysical and biochemical properties of bivalent bispecific series of engineered VHH-based IgG-like antibodies. Format designs are indicated as well as expression yields post protein A purification and size exclusion chromatography target monomer peaks. Affinities as determined by biolayer interferometry are also given.

BiBi9	B (Kappa + 10 aa linker)	EGFR (9G8)	HER2	1.79E-09	1.73E-08	73	150

exceptionally good as well as bad aggregation properties were grafted onto the kappa and lambda backbone, it is tempting to speculate that this observation is more related to the paratopes themselves and the individual orientation of the VHHs in the overall architecture. In terms of biochemical properties, all analyzed molecules retained their affinities as compared to the monospecific control molecules (Table 1, Ctrl1-4; Table 2). Moreover, all bivalent bispecifics were able to engage in simultaneous binding (Fig. S3). As expected, when EGFR-specific VHH 9G8 was placed onto the heavy chain and the HER2-specific VHH was engrafted onto the kappa constant chain (BiBi1), simultaneous binding was again compromised (Fig. S9). Similar to the monovalent counterpart, this decline in binding capacity could be partially compensated by employing a 10 amino acid linker (BiBi9).

Expression and characterization of trispecific IgG-like VHH-based SEEDbodies

By simply placing a third VHH-derived moiety on top of the hinge region of the GA chain of the IgG-like VHH-based SEEDbody, we also set out to characterize this platform approach with respect to trispecific targeting (Figure 1(d), Table 3, MoTri series of molecules). In this regard, we wanted to directly compare this monovalent trispecific format with another format enabling trispecificity, in which the light-chain-based VHH is bivalent (Figure 1(c), Table 3, BiTri entries). To this end, SEED molecules were produced, where on each chain of the SEEDbody (AG and GA) a different VHH was engrafted on domain CH1. Simultaneous expression of a VHH engrafted onto the constant region of the light chain results in the pairing of both heavy chain-derived paratopes with the light chain-embedded paratope.

The strictly monovalent trispecific SEEDbodies displayed rather beneficial biophysical properties. Expression yields were constantly in the triple-digit mg per liter scale, and SEC profiles (Fig. S8) were reasonably acceptable, even when compared to the bivalent bispecific format (Table 2, BiBi series of molecules). This was to our surprise, since the sophisticated architecture of this asymmetric trispecific format seems to be fairly complex, at least in direct comparison to the bivalent bispecific approach, where not even a heavy chain heterodimerization technique is needed. However, this is in stark

contrast to the bivalent trispecific format (Table 3, BiTri series of entries). While expression yields were still reasonable, the SEC profiles, i.e., the target peaks, declined significantly, to only little more than 50% for some of the scrutinized molecules, clearly demonstrating strongly compromised biophysical properties. Noteworthy, these detrimental attributes are not only related to aggregation propensities but also due to significant amounts of low molecular weight species, clearly indicating mis-assembled molecules (Fig. S8).

Similar to the design of the bivalent bispecific format (BiBi series), the expression of entities of the bivalent trispecific series (BiTri) result in a symmetric overall architecture of the respective molecules. On the contrary, molecules of the MoBi and MoTri series that in general display more adequate biophysical properties, i.e., target monomer peaks in SEC, are asymmetric by design. Consequently, this suggests that an asymmetric molecule design of the herein presented 'plug-and-play' approach generally results in fairly favorable biophysical attributes.

With respect to biochemical properties, as anticipated, no significant decline of affinities was detected for each embedded VHH against the respective antigen. Likewise, all molecules analyzed engaged in trispecific simultaneous binding against each antigen, as exemplarily shown for molecules MoTri 2 and BiTri4 (Figure 7, Fig. S3).

Discussion

Bi- and multispecific antibodies have recently emerged as promising molecules for disease treatment.^{5,6} In this respect, bi- and multispecific entities opened up new avenues to address the complex biology of several diseases more appropriately compared to monospecific antibodies.²⁶⁻³⁰ Accordingly, an unparalleled repertoire of different antibody formats was developed, each with its own characteristics, beneficial attributes, and limitations, as elegantly reviewed elsewhere.^{5,6} In this context, VHH-derived constructs afford the benefit of multiple reformatting options.^{16,17} Moreover, antigen-specific single-domain antibodies from camelids can be readily obtained by combining animal immunization with antibody display systems enabling genotype-phenotype coupling.^{10,11} However, for therapeutic use in patients, it must be noted that the foreign nature of camelid-derived VHHs bears the

Table 3. Biophysical and biochemical properties of trispecific VHH-derived SEEDbodies. Format designs are indicated as well as expression yields post protein A purification and size exclusion chromatography target monomer peaks. Affinities as determined by biolayer interferometry are also given.

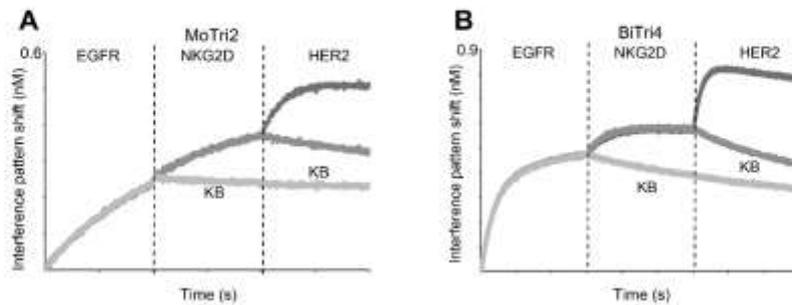

Figure 7. Simultaneous trispecific antigen binding of (a) monovalent trispecific VHH-derived IgG-like antibody MoTri2 and (b) bivalent trispecific entity BiTri4 against 50 nM EGFR followed by 50 nM NKG2D and 50 nM HER2. For each association step a control in KB is shown.

risk of immunogenicity. In this respect, Vincke *et al.* described a general strategy for humanization.³¹ Currently, multiple VHH-derived entities are being investigated in clinical trials, and bivalent single-domain caplacizumab (Cablivi[®]) has been approved for the treatment of patients with acquired thrombotic thrombocytopenic purpura by the FDA.^{14,15} To the best of our knowledge, most if not all of these molecules were humanized. This gives clear evidence that the risk of substantial immunogenicity can be circumvented by humanization.

Within this work, we aimed at characterizing a VHH-based platform for facile construction of different IgG-like bi- and multispecific antibody constructs that differ significantly among themselves with respect to their biophysical characteristics as well as biochemical properties. Essentially, the main building block in this platform approach was described some time ago by Baty and coworkers.¹⁸ We set out to investigate to what extent this approach can be broadened for the generation of bi- and trispecific moieties comprising flexible valencies without fundamentally compromising essential intrinsic attributes, for instance aggregation behavior or binding capacities.

In regard to biophysical properties, it is remarkable that expression yields, as determined after protein A purification of most of the bi- and trispecific molecules, were fairly high compared to other technologies reported.³²⁻³⁴ Most importantly, yields were quite similar to the parental molecules, i.e., controls. This was also true for aggregation onset temperatures, indicating in general adequate stabilities of VHHs when engrafted into the Fab-based architecture. With respect to aggregate formation and potential mis-assembly of molecules, substantial differences were determined for the different herein described formats. In general, asymmetric formats, i.e., monovalent IgG-like VHH-based bispecific antibodies as well as strictly monovalent trispecific SEEDbodies, displayed rather favorable aggregation propensities while symmetric formats tended to be more prone to malfunction. In this context, SEC profiles for bivalent bispecific VHH-based IgG-like antibodies indicated still acceptable target monomer formation. For the bivalent (for the light chain) trispecific format (BiTri series of molecules), however, aggregate formation and mis-assembled molecules (low molecular weight species) were fundamentally worsened clearly disqualifying this format for further consideration.

It is important to note that for all the different VHHs that were embedded into the Fab scaffold, overall affinities were

quite similar to the control molecules. The interference pattern shift, however, was slightly decreased in every instance, indeed indicating impeded binding capacities to a minor extent for engrafted paratopes. Yet, this effect appears to be almost neglectable, since cellular binding did not seem to be impaired substantially. From a functional aspect, we were able to demonstrate that both Fab-engrafted single-domain paratopes can engage in simultaneous binding in a cellular context. This is especially vital for several therapeutic concepts that involve targeting of different cell types at the same time, such as effector cell redirection.³⁵⁻³⁷ Similar to Baty and coworkers,¹⁸ we were able to show that the overall architecture of this platform clearly allows for effector cell recruitment enabling tumor cell killing.

Furthermore, we report that for one VHH analyzed (HER2) in this platform approach, engraftment onto the kappa chain causes a substantial loss of affinity when the other embedded VHH (EGFR, clone 9G8) already engages in antigen binding. Positioning effects have also been described for other bispecific platform technologies, for instance, DVD-Igs or TriFabs and others,^{34,38-40} typically resulting in compromised binding affinities. Surprisingly, the individual binding affinity of the engrafted paratope against the respective antigen was not impaired substantially. Accordingly, this positioning effect does not diminish the binding capacity of the individual paratope per se, but only in the context of simultaneous binding. We were also able to show that a 10 amino acid linker between the impacted VHH and the kappa chain reversed this effect. In addition, this affinity sink in simultaneous binding was not observed in the lambda context. Stanfield and colleagues were able to demonstrate that Fabs comprising lambda chains tend to have hypervariable elbow angles, i.e., angles between the variable regions and the constant domains.⁴¹ On average, these elbow bends are significantly wider than those of kappa chain Fabs. Presumably, this is due to a glycine insertion at the switch region between the variable domain of the light chain and the constant region that appears to increase the flexibility of the Fab. This increased flexibility might be the main reason why this positioning effect was not detected for VHH engrafted onto the lambda light chain. Thus, this gives clear evidence that positioning effects can be circumvented either by simple linker design or by replacing the kappa chain for a lambda chain.

Ultimately, the herein presented VHH-based IgG-like bi- and trispecific antibody platform appears to have the versatility to combine up to three preexisting VHHs in one multispecific molecule. We demonstrated that the different described formats, except for molecules of the BiTri series seem to comprise acceptable properties and that early-stage 'developability' is feasible. Essentially, this 'plug-and-play' platform affords the benefit to tailor multispecific entities with respect to their biophysical and biochemical properties.

Materials and methods

Antibody expression and purification

All constructs were designed in-house and synthesized by GeneArt (Thermo Fisher Scientific). In general, all antibody-like constructs and SEED molecules were cloned into pTT5 plasmid backbone (GeneArt/Thermo Fisher Scientific). For SEEDbody expression, the RF mutation was introduced to prevent the formation of undesired GA:GA chain homodimers.²⁵ Expi293 cells were transiently transfected with expression vectors according to the manufacturer's recommendations (Thermo Fisher Scientific). Five days post transfection, the antibody-containing supernatants were harvested by centrifugation and purified via MabSelect antibody purification chromatography resin (GE Healthcare). A final dialysis step using Pur-A-Lyzer™ Maxi 3500 Dialysis Kit (Sigma Aldrich/Merck KGaA) was performed at 4°C for 24 h to ensure sample formulation in phosphate-buffered saline (PBS) pH 6.8, followed by an additional protein concentration step via Amicon Ultra-4 Centrifugal Filters (EMD Millipore), if necessary. UV-Vis spectrophotometric measurement (Nanodrop ND-1000, Peqlab) was used to determine protein concentrations. Additionally, the expressed antibodies were analyzed in duplicates by differential scanning fluorometry on Prometheus NT.48 (Nanotemper Technologies) to evaluate the stability of expressed molecules. When measuring the thermal stability of proteins, multiple values like T_{onset} , T_m and T_{agg} can be reported. The lowest temperature at which the protein starts to unfold is defined as the T_{onset} while T_m is the melting point at which 50% of the thermally least stable domain is unfolded. Multiple unfolding events of protein domains can overlap, and therefore T_m can vary more between similar constructs than T_{onset} . Thus, we chose T_{onset} as a discriminator to compare the thermal stability of multiple protein variants. Furthermore, aggregate formation was analyzed by analytical SEC of 10 µg protein per sample, using a TSKgel SuperSW3000 column (4.6 × 300 mm, Tosoh Bioscience LLC) in an Agilent HPLC system with a flow rate of 0.35 ml/min.

Biolayer Interferometry

Simultaneous binding, periodic binding, epitope binning, as well as kinetic measurements were performed on the Octet RED96 system (ForteBio, Pall Life Science) at 25°C and 1000 rpm agitation. For kinetic analysis, the antibody-like molecules to be analyzed were loaded on anti-human-FC (AHC) Biosensors at 5 µg/mL in PBS for 3 min. Afterward, tips were transferred to kinetics buffer (KB; PBS, 0.1% Tween-20 and 1% bovine serum albumin, BSA) for 60 s for sensor rinsing. Association to the corresponding antigen human

EGFR (in-house), human NKG2D (Sino Biological, Cat: 10575-H07B) and human HER2 (Sino Biological, Cat: 10004-H08H) in varying concentrations ranging from 12.5 nM to 50 nM in KB was measured for 300 s followed by dissociation in KB for 300 s. In each experiment, one negative control was included where the association was monitored against an unrelated antigen (50 nM in KB). Moreover, one reference value was included with the association in KB instead of the antigen. Resulting data were fitted and analyzed with ForteBio data analysis software 8.0 using a 1:1 binding model after Savitzky-Golay filtering.

To demonstrate simultaneous antigen binding, respective antibody-like molecules were captured to the surface of anti-human IgG Fc (AHC) biosensors for 3 min at a concentration of 5 µg/ml and sensor rinsing was conducted in KB for 60 s. Afterward, sensors were transferred to first antigen solution (50 nM in KB) and incubated for 100 s to 300 s, followed by an association in second antigen solution for 100 s to 300 s (50 nM in KB) and consecutively, when applicable, in antigen three for 100 s to 300 s (50 nM in KB).

Furthermore, for the kinetic measurements with EGFR bound in saturation or without prior EGFR binding the antibody was loaded on anti-Penta His biosensors for 180 s, followed by 60 s of sensor rinsing in KB. Afterward, 500 nM EGFR was used to saturate the binding capacity of the antibody for 300 s. Accordingly, KB was used instead of EGFR for the measurements without EGFR binding in saturation. Afterward, the association was determined against HER2 (300 s) using varying concentrations from 0 to 50 nM. To avoid a dissociation of EGFR in this step, 50 nM EGFR was used for every HER2 concentration tested. For the following dissociation step (300 s), EGFR was also used at 50 nM to assess dissociation against HER2 only.

For the assessment of periodic antigen-binding antibodies were loaded on Anti-human-Fc (AHC) biosensors at 1 µg/mL for 3 min. After 60 s of sensor rinsing in KB association was analyzed at a concentration of 50 nM for 300 s followed by a dissociation step in KB for 30 min. The association and dissociation steps were consecutively repeated for six times in total.

Epitope binning analysis was performed by loading EGFR (ECD) via its histidine-tag on anti-Penta His (HIS1K) biosensors at 3 µg/mL in PBS for 3 min. After a step of sensor rinsing in KB for 60 s association to the respective EGFR-specific molecule (at 100 nM) was performed (Table 1, Ctrl1 or Ctrl4), followed by either dissociation in KB or by another association step with the second EGFR-derived VHH (at 100 nM). One negative control was measured in parallel, where the sensor was not loaded with antigen to check for unspecific association of the antibodies to the biosensor. Moreover, one reference value using buffer instead of antibody association was measured as 'association baseline.'

Flow cytometry

Flow cytometric analyses were conducted on the Guava® easyCyte 12HT device (Merck Millipore) using guavaSoft 3.2 Software. For each experiment, 5000 events/well were measured.

To determine cellular binding properties of the expressed antibodies, EGFR-positive MDA-MB-468, HER2-positive SK-BR-3, and EGFR/HER2 negative CHO cells were used. For staining assays, 1×10^5 cells per well were seeded. After two consecutive washing steps with PBS+1% BSA, cells were incubated for 1 h on ice with antibodies in varying concentrations. Afterward, two additional washing steps with PBS+1% BSA were performed, followed by staining with a detection antibody at 4°C for another 1 h. Cell binding was identified with Alexa Fluor® 488 AffiniPure F(ab')₂ Fragment Goat Anti-Human IgG, Fcγ fragment specific antibody (Jackson ImmunoResearch, Cat: 109-546-008) for EGFR- and HER2-positive cells lines, respectively, as well as Alexa Fluor® 488 AffiniPure Fab Fragment Goat Anti-Human IgG (H + L) antibody (Jackson ImmunoResearch, Cat: 109-547-003) for the negative CHO cells. After two washing steps with PBS+1% BSA, dead cells were stained via 20 µg/ml propidium iodide (Invitrogen) addition in a total volume of 200 µl/well. Additionally, a negative control without antibody treatment as well as a control using the detection antibody only and a control using in-house produced cetuximab (Erbix™) or trastuzumab (Herceptin™) as positive reaction, was conducted in each experiment for each cell line (not shown).

For the investigation of simultaneous cellular binding, EGFR-positive MDA-MB-468 cells were stained prior to the assay with CellTracker™ Deep Red Dye (ThermoFisher). To this end, the cells were harvested and washed once in PBS before staining 1×10^6 cells/ml with the reagent (1:1000 in PBS) for 15 min at 37°C in the dark. Following incubation, the cells were washed once with respective complete medium and finally washed once with PBS+1% BSA. This staining procedure was performed accordingly for HER2-positive SK-BR-3 cells, except using CellTrace™ CFSE Cell Proliferation Kit as dye (1:100'000 in PBS). For both cell lines, 1×10^5 cells each were combined and inserted per well. As controls, wells containing just one cell line were used, allowing for gating the single-cell populations. After a washing step with PBS+1% BSA, cells were incubated for 1 h on ice with the antibodies in varying concentrations ranging from 0.1 nM to 1 µM. Finally, two more washing steps with PBS+1% BSA were conducted and the cells were resuspended in 200 µl volume for flow cytometric measurements. By applying a rectangular gate, the single-cell populations were discriminated from the simultaneously bound cells forming duplets and showing a positive signal for both fluorescence dyes.

Tumor cell killing assay

PBMCs cells were isolated from whole blood samples of healthy human donors by density gradient centrifugation with consecutive NK cell isolation using EasySep™ Human NK Cell Isolation Kit (Stemcell Technologies). Effector cells were adjusted to 0.625×10^6 vc/ml after overnight incubation in complete medium containing 100 U/ml recombinant human interleukin-2 (R&D systems). A431 target cells were prepared in parallel by staining with CellTracker™ Deep Red Dye (ThermoFisher) according to the manufacturer's instructions. For the assay, 20 µl target cells (resulting in 2'500 c/well) were seeded in 384-well clear bottom

microtiter plate (Greiner Bio-One) and incubated for 3 h. Afterward, 5 µl of the bispecific antibodies were added with varying concentrations ranging from 10^{-7} M to 10^{-12} M followed by the addition of 20 µl NK cell suspension, resulting in an effector cell to target cell (E:T) ratio of 5:1. Finally, SYTOX™ Green Dead Cell Stain (Invitrogen) was added to the assay.

NK cells cultivated with A431 cells in the absence of antibodies as well as A431 cultivated with antibodies without adding NK cells as well as A431 cells with the highest antibody concentration without NK cells were used as controls. To assess maximum tumor cell lysis, staurosporine was dispensed to A431 cells as another control with a final concentration of 30 µM. For the incubation (24 h) and on-line imaging of the assay an Incucyte® Live Cell Analysis System (Sartorius) was used. Overlay (green and red fluorescence) signals per well allowed for analysis of dead target cells only.

Professorship-Program) to MP.

Abstract

Activating Natural Killer (NK) cell receptors represent promising target structures to elicit potent anti-tumor immune responses. Here, novel immunoligands were generated that bridge the activating NK cell receptor NKp30 on NK cells with epidermal growth factor receptor (EGFR) on tumor cells in a bispecific IgG-like format based on affinity-optimized versions of B7-H6 and the Fab arm derived from Cetuximab. To enhance NKp30 binding, the solitary *N*-terminal IgV domain of B7-H6 (Δ B7-H6) was affinity matured by an evolutionary library approach combined with yeast surface display. Biochemical and functional characterization of 36 of these novel Δ B7-H6-derived NK cell engagers revealed an up to 45-fold enhanced affinity for NKp30 and significantly improved NK cell-mediated, EGFR-dependent killing of tumor cells compared to the NK cell engager based on the wild-type Δ B7-H6 domain. In this regard, potencies (EC_{50} killing) of the best immunoligands were substantially improved by up to 87-fold. Moreover, release of interferon- γ (IFN- γ) and tumor necrosis factor- α (TNF- α) was significantly increased. Importantly, equipment of the Δ B7-H6-based NK cell engagers with a human IgG1 Fc part competent in Fc receptor binding resulted in an almost 10-fold superior killing of EGFR-overexpressing tumor cells compared to molecules either triggering Fc γ RIIIa or NKp30. Additionally, INF- γ and TNF- α release was increased compared to molecules solely triggering Fc γ RIIIa including the clinically approved antibody Cetuximab. Thus, incorporating affinity-matured ligands for NK cell activating receptors might represent an effective strategy for the generation of potent novel therapeutic agents with unique effector functions in cancer immunotherapy.

Key points

- B7-H6 was affinity matured by yeast surface display
- NK cell engagers harboring optimized B7-H6 have improved cytotoxic capacities
- NK cell engagers based on improved B7-H6 display a differentiated cytokine profile

Introduction

Natural killer (NK) cells are innate lymphocytes that recognize discontinuity and danger in multiple tissue compartments by integrating positive and negative signals (1). The negative signals are generally mediated by the interaction between self MHC-I on tissues and either Killer-Immunoglobulin-like Receptor (KIR) family members or Natural Killer Group 2A (NKG2A) (2). Positive signals are transduced via the interaction of an array of NK activation receptors including the Natural Cytotoxicity Receptors (NCRs; NKp30, NKp46, NKp44), NKG2D and DNAM-1 as well as costimulatory molecules including 4-1BB and their ligands (3–5). For the NCRs and NKG2D, many of the ligands are 'danger signals' that are upregulated on stressed and diseased tissues including viral infected cells and tumor cells (6-8). Another mechanism by which NK cells are activated is the bridging of the low affinity activating FcγRIIIa (CD16a) on NK cells with cells opsonized with IgG antibodies or bispecific antibodies (9, 10). Unlike the NCRs and NKG2D, signaling through FcγRIIIa is often more robust in resting NK cells but is modulated by multiple variables including functionally distinct polymorphic variants of FcγRIIIa as well as competition for binding with circulating IgG (11–15). Ultimately, the balance of activation and inhibitory signal determines whether an NK cell will become activated. As such, NK cells have an endogenous capacity to differentiate between healthy and diseased tissues (16, 17).

Recently, several early clinical trials employing the adoptive transfer of wild-type or genetically modified (e.g. CAR) NK cells either alone or in combination with antibodies as a therapeutic modality for cancer have been initiated with encouraging early results for hematological malignancies (18–21). Although adoptive cell therapy with *ex vivo* activated NK cells represents a promising approach (22) the logistic complexity has also driven the development of NK cell-directed antibody-based approaches to cancer immunotherapy such as bispecific or trifunctional entities that form a bridge between an activation receptor on NK cells and a tumor

associated antigen (TAA) on the tumor cell, referred to as NK cell engager or immunoligand (11, 23, 24). Bispecific antibodies targeting a TAA (e.g. CD20) and NKp46 (25), NKG2D (26) and NKp30 (27, 28) either via an antibody moiety or a recombinant form of the ectodomain of a ligand (e.g. ULBP2) (29) have demonstrated potent target-dependent cytotoxicity and cytokine release *in vitro*.

NKp30 is an activation receptor expressed on the majority of NK cells (30). Its cell bound ligand, B7-H6 is upregulated on tumor cells and absent on most normal cells (7). The other less well characterized ligand is HLA-B-associated transcript 3 (BAT3)/Bcl2-associated athanogene 6 (BAG6), which is expressed in the nucleus and can be transported to the plasma membrane or released in exosomes (31, 32). Importantly, decreased NKp30 expression has been correlated with reduced survival in AML (33) and a lower number of NK cells expressing NKp30 were found in patients with gastric or breast cancer compared to healthy donors (34), (35). Together, these data suggest that the NKp30 receptor axis may play an important role in tumor surveillance of different tumor entities. Therefore, potent strategies modulating the NKp30 axis may represent promising approaches to promote antitumor NK cell responses.

In this work, we designed human EGFR x NKp30 NK cell engagers (i.e. immunoligands) to trigger NKp30-mediated tumor cell elimination using bispecific antibody-like fusion proteins containing a humanized Fab variant derived from Cetuximab and a panel of affinity-optimized variants of the N-terminal Ig-like V-type domain of B7-H6 (Δ B7-H6) engineered by yeast surface display. The bispecific NK cell engagers harboring affinity-matured variants facilitated substantially increased NK cell-mediated killing of tumor cells of up to 87-fold compared to molecules harboring the wild-type Δ B7-H6 domain. Importantly, target-dependent cytokine release of TNF- α and IFN- γ was also fundamentally elevated. Intriguingly, this proinflammatory cytokine release was also significantly increased compared to therapeutic antibody Cetuximab. Furthermore, we demonstrated that expression of Δ B7-H6-based

immunoligands in an effector competent human IgG1 backbone further enhanced killing of EGFR-overexpressing tumor cells by one order of magnitude compared to molecules either triggering FcγRIIIa or NKp30 alone. Taken together, our data suggests that an EGFR x NKp30 NK cell engager based on affinity engineered variants of B7-H6 can elicit potent NK cell-mediated lysis with a differentiated profile of released cytokines that could be envisioned to result in targeted inflammation of tumors.

Materials and Methods

Yeast surface display and affinity maturation of Δ B7-H6 variants

Saccharomyces cerevisiae strain EBY100 (*MATa URA3-52 trp1 leu2 Δ 1 his3 Δ 200 pep4::HIS3 prb1 Δ 1.6R can1 GAL (pIU211:URA3)*) (Thermo Fisher Scientific) was used for yeast surface display. Initially, cells were cultivated in YPD medium composed of 20 g/L peptone, 20 g/L dextrose and 10 g/L yeast extract supplemented with 10 ml/L penicillin-streptomycin (Gibco). Homologous recombination in yeast (gap repair cloning) was utilized for generation of the Δ B7-H6 library. Eight residues of the N-terminal IgV domain of B7-H6 at the binding interface of B7-H6 and NKp30 (pdb: 4ZSO) were randomized via TRIM technology at GeneArt (Thermo Fisher Scientific). As described previously, sequences were cloned in a pYD-derived backbone as destination vector (pDest) in frame with Aga2p C-terminally carrying an HA epitope to enable yeast cell surface presentation and detection of full-length molecules (36). Cells harboring library plasmids were cultivated at 30°C and 120 rpm in minimal SD-base medium with dropout mix composed of all essential amino acids except from tryptophan to maintain selection pressure according to the manufacturer's instructions (Clontech), supplemented with 5.4 g/L Na₂HPO₄ and 8.6 g/L NaH₂PO₄ × H₂O. Δ B7-H6 expression for library sorting was achieved by culture of 10⁷ cells/ml for 48 h at 20°C in SG medium with dropout mix wherein glucose was replaced by galactose (Clontech) and 10% (w/v) polyethylene glycol 8000 (PEG 8000). NKp30 binding of yeast surface expressed Δ B7-H6 was monitored by indirect immunofluorescence using his-tagged NKp30 (Abcam) in combination with Penta-His Alexa Fluor 647 antibody (Qiagen, diluted 1:20). Simultaneously, Δ B7-H6 surface expression was detected by an anti-HA-PE antibody (Abcam, diluted 1:20). Detection and sorting of yeast candidates was done on a SH800S cell sorter (Sony) using a 70 μ m sorting chip in three successive rounds. For the first sorting round 10⁸ yeast cells were incubated with 1 μ M NKp30 followed by a second round with 100 nM NKp30 and a third round with 50 nM NKp30.

Incubation was performed for 1 h on ice prior washing with PBS and sorting. For the second and third sorting round, cells were incubated for 30 min in 3 ml and 30 ml PBS, respectively, to increase sorting stringencies.

Expression and purification of NK cell engagers

Unique Δ B7-H6 sequences were fused to SEED AG chain and cloned into pTT5 (either in house or at GeneArt/Thermo Fisher Scientific) to allow full-length bispecific SEED production by combination with humanized Cetuximab (hu225) Fab on the SEED GA chain. Molecules were either produced in an effector silenced backbone by introduction of amino acid exchanges L234A, L235A, P329G (SEED_PGLALA) or in an effector competent IgG1 backbone (SEED). To this end, Expi293 cells were transiently transfected with respective expression vectors according to manufacturer's instructions (Thermo Fisher Scientific). Antibody containing supernatants were harvested and purified via MabSelect antibody purification chromatography resin (GE Healthcare). NK cell engagers were dialyzed overnight against PBS pH 6.8 using Pur-A-Lyzer™ Maxi 3500 Dialysis Kit (Sigma Aldrich). Protein concentrations were determined by UV-Vis spectrophotometric measurement (Nanodrop ND-1000, Peqlab) and thermal stabilities were evaluated by differential scanning fluorimetry on a Prometheus NT.48 (Nanotemper Technologies). To assess purity and aggregations, proteins were analyzed by analytical size exclusion chromatography with a TSKgel SuperSW3000 column (4.6×300 mm, Tosoh Bioscience LLC) in an Agilent HPLC system with a flow rate of 0.35 ml/min.

Biolayer interferometry (BLI)

Kinetic measurements were performed on Octet RED96 system (ForteBio, Pall Life Science) at 25°C and 1000 rpm. Immunoligands (5 µg/ml in PBS) were loaded on anti-human Fc biosensors for 5 min followed by 60 s rinsing the sensor with kinetics buffer (KB; PBS + 0.1 %

Tween-20 + 1% BSA). Afterwards, association to human NKp30 (Abcam) in varying concentrations (15.6-1000 nM) was measured for 60 s followed by dissociation measurement for 180 s in KB. An irrelevant antigen was measured as negative control in each experiment. Data was fitted and analyzed with ForteBio data analysis software 8.0 using a 1:1 binding model after Savitzky-Golay filtering.

Cell culture

EGFR-expressing epidermoid carcinoma cell line A431 and non-small cell lung carcinoma cell line A549 were obtained from DSMZ and cultured in RPMI 1640 Glutamax-I or Dulbecco's Modified Eagle's medium supplemented with 10% FCS, 100 U/ml penicillin and 100 mg/ml streptomycin (R10+ and D10+), respectively (all components from Thermo Fisher Scientific). Human Expi293 cells for production of immunoligands were cultivated in suspension with complete Expi293 expression medium (Thermo Fisher Scientific).

Tumor cell killings assays

Experiments were approved by the Ethics Committee of the Christian-Albrechts-University of Kiel (Kiel, Germany) and in accordance with Merck internal guidelines and with the Declaration of Helsinki. Preparation of PBMCs from healthy donors was performed as previously described after receiving written informed consent (37). NK cells were isolated by negative selection using NK cell isolation kit (Miltenyi Biotech) and maintained overnight at a density of 2×10^6 cells/ml in R10+ medium. Cytotoxicity was analyzed in standard 4 h ^{51}Cr release assays performed in 96-well microtiter plates in a total volume of 200 μl as described previously (37). Human PBMCs or purified NK cells were used as effector cells at effector-to-target cell (E:T) ratios of 80:1 and 10:1, respectively. NK cell engagers or Cetuximab were applied at concentrations indicated. For blocking experiments, cells were pre-incubated for 15 min with 50 $\mu\text{g/ml}$ of either anti-NKp30 mouse IgG2A antibody (mouse IgG2A isotype

control antibody was used as a control in these experiments; both R&D Systems) to block NKp30 binding on NK cells or oa_hu225-SEED-PGLALA to block EGFR binding on tumor cells before the respective NK cell engagers were added. Percent lysis was calculated as follows from counts per minute (cpm): % lysis = (experimental cpm-basal cpm)/(maximal cpm-basal cpm)x100 and normalized (0 % = % lysis of oa_hu225-SEED-PGLALA control molecule, 100 % = % lysis of Cetuximab at saturating concentration) to allow for direct comparison of affinity-matured ΔB7-H6-derived molecules between individual donors. Inhibited lysis was calculated as follows: $100\% - (\% \text{ lysis}_{\text{blocked}} * 100) / \% \text{ lysis}$.

Cytokine release assay

For cytokine release assays, NK cells were isolated with EasySep™ Human NK Cell Isolation Kit (Stemcell Technologies) and incubated overnight in AIM V medium containing 100 U/ml recombinant human interleukin-2 (R&D Systems). 2.500 A431 cells were seeded in 384-well microtiter plates (Greiner Bio-One) and incubated for 3 h. Immunoligands were added to a final concentration of 85 nM followed by addition of NK cells at an E:T ratio of 5:1. After 24 h, supernatants were analyzed using human IFN-γ or TNF-α HTRF kit (Cisbio) according to manufacturer's instructions. Plates were measured with PHERAstar FSX (BMG Labtech) and data were analyzed by MARS software (v.3.32, BMG) enabling a 4-parameter logistic (4PL 1/y) model fitting of the standard curve.

NK cell activation assay

20.000 A431 cells/well were seeded in 96-well V-bottom microtiter plates (Thermo Fisher Scientific) and incubated for 3 h prior addition of 100.000 NK cells/well (E:T ratio of 5:1), which were treated with 100 U/ml recombinant human interleukin-2 overnight. Immunoligands were added at a final concentration of 85 nM followed by 24 h incubation at 37°C. Cells were washed two times with PBS + 1 % BSA prior incubation with LIVE/DEAD™ Fixable Near-IR

Dead Cell Stain (Thermo Fisher Scientific), anti-human CD56-PE (Miltenyi Biotec) and anti-human CD69-APC (Abcam) for 1 h on ice. After washing, cells were measured via flow cytometry with Intellicyt® iQue® Screener Plus (Sartorius). For compensation of fluorochromes antibody capturing analysis beads (OneComp eBeads™ Compensation Beads, Thermo Fisher Scientific) were employed according to the manufacturer's instructions. The gating strategy is shown in supplementary figure 1 (**Fig. S1**).

Data processing and statistical analysis

Graphical and statistical analyses were performed with GraphPad Prism 8 software. *P*-values were calculated employing repeated measures ANOVA and the Bonferroni or Tukey post-test as recommended, or the student's *t*-test when appropriate. $p \leq 0.05$ were regarded as statistically significant.

Results

Extracellular IgV domain of B7-H6 is sufficient to engage NK cells for tumor cell lysis

In previous studies, it was shown that B7-H6 scFv fusion proteins trigger NK cell-mediated lysis of tumor cells (28, 38). Since the NKp30 binding site is located in the IgV domain of B7-H6, we hypothesized that this isolated domain alone is sufficient to trigger NK cell activation and tumor cell killing. To address this question, the *N*-terminal Ig-like V-type domain (Asp25-Ala144) of the extracellular region of B7-H6 (termed Δ B7-H6) was used to design a novel EGFR-targeting NKp30 NK cell engager (**Fig. 1A, B**). To completely abolish Fc-mediated immune effector functions, the LALA-PG amino acid exchanges (L234A, L235A, P329G) were introduced (39). Kinetic studies of this Δ B7-H6_{wt}-SEED-PGLALA molecule revealed functional binding to NKp30 (**Fig. 1C**), in accordance with previously published work (40, 41). Most importantly, significant lysis of EGFR-expressing A431 tumor cells was triggered by this novel immunoligand (**Fig. 1D**), demonstrating that the isolated Δ B7-H6 domain is sufficient to promote NK cell-mediated lysis of target cells. However, the extent of tumor cell lysis with the monovalent EGFR binding NK cell engager Δ B7-H6_{wt}-SEED-PGLALA ($EC_{50} = 244.8$ pM) was significantly reduced compared to a similarly designed one-armed (oa) EGFR-targeting molecule (oa_{hu225}-SEED) lacking the NKp30 binding domain but harboring an active IgG1 Fc region triggering Fc γ RIIIa, one of the strongest known trigger molecules expressed on NK cells ($EC_{50} = 27.8$ pM).

Affinity maturation of the B7-H6 IgV domain by yeast display

In order to improve the cytotoxic activity of the novel Δ B7-H6-based NK cell engager, we designed a focused combinatorial mutant library of Δ B7-H6 for yeast surface display using trinucleotide mutagenesis technology with the aim of enhancing affinity of Δ B7-H6 for NKp30. Δ B7-H6 was displayed successfully and showed specific binding to recombinant NKp30

(**Fig. S2**). Based on the co-crystal structure of B7-H6 and NKp30 eight residues of B7-H6 (Ser60, Gly62, Phe82, Gly83, Val125, Thr127, Leu129 and Lys130) at the contact interface with NKp30 were chosen for library design (**Fig. 2A**). Randomization of these residues was designed in a semi-rational way such that only amino acids that were thought to be potentially beneficial for binding affinity were taken into account. As shown in **Fig. 2B**, the synthesized library matched fairly well with the initial design showing only little bias. The resulting library (comprising approximately 1×10^7 unique clones) was sorted by fluorescence-activated cell sorting (FACS) against recombinant NKp30 to isolate variants with significantly enhanced affinities (**Fig. 2C**). To this end, a two-dimensional labeling strategy was employed to simultaneously detect full-length Δ B7-H6 and binding to NKp30. Due to the low affinity interaction of B7-H6 and NKp30, that was reported to be in the μ M range (40), an NKp30 protein concentration of 1μ M was utilized in the first selection round and subsequently reduced to 100 nM and 50 nM, respectively (**Fig. 2C**). Library output after three rounds of selection was analyzed for NKp30 binding in direct comparison with the wild-type Δ B7-H6 and revealed improved NKp30 binding of the vast majority of affinity-matured Δ B7-H6 clones (**Fig. S2C, D**). After sequencing of approximately 200 clones from sorting round two and three, we were able to identify 47 unique clones (**Tab. SI**). Interestingly, none of those comprised mutations at positions Thr127 or Lys130. Consequently, it is tempting to speculate that these two residues are essential for B7-H6 binding to NKp30 or for structural integrity of the molecule.

Generation and characterization of affinity-matured Δ B7-H6 NK cell engagers

All 47 unique affinity-matured Δ B7-H6 clones were reformatted as Fc-silenced SEEDbodies with monovalent EGFR binding by using the humanized Fab arm of Cetuximab (hu225) as shown already for the wild-type Δ B7-H6 NK cell engager (**Fig. 1B**). As summarized in **Table SI**, besides two variants that showed either very low expression (S2#8) or no productivity

at all (S2#9), expression yields of all variants after protein A chromatography were in the double to triple digit milligram per liter scale. This is generally acceptable for transient expression of bifunctional antibody-like fusion proteins. Moreover, melting temperatures of all variants were quite similar to the denaturation point of the SEEDbody comprising Δ B7-H6 wild-type domain (**Table SI**), giving clear evidence that no substantial loss in stability was observed by introducing mutations into Δ B7-H6. Most importantly, the vast majority of the affinity-matured variants showed significantly enhanced affinities for NKp30 of up to 45.1-fold (S3#18) compared to the wild-type Δ B7-H6 NK cell engager (**Table I, Fig. S2E**). In general, improved off-rates contributed substantially more to the overall affinity maturation than modulations of on-rates of the Δ B7-H6 SEED PGLALA immunoligands. Interestingly, variant S3#13 that did not bind NKp30, was the only clone isolated that contained a mutation of Gly62 (Gly62Ile). This observation suggests that in addition to Thr127 or Lys130, Gly62 may also be indispensable for Δ B7-H6 binding to NKp30. For subsequent functional evaluation of the affinity-matured Δ B7-H6-derived NK cell engagers, we focused on immunoligands showing at least 85 % monomers (i.e. a maximum of 15 % aggregates) as determined by size exclusion chromatography. Accordingly, 36 affinity-matured Δ B7-H6 NK cell engagers were selected for functional experiments (**Table I**).

Affinity-matured Δ B7-H6 immunoligands elicit strongly enhanced NK cell-mediated cytotoxicity against EGFR-expressing tumor cells

As an initial screening, the 36 remaining Δ B7-H6, EGFR-targeting NK cell engagers were tested for their capacity to mediate tumor cell killing using PBMCs (containing 5-20 % NK cells) from healthy donors as effector cells and the EGFR-positive tumor cell line A431 as target cells in chromium release assays. To allow comparison and ranking of the 36 molecules, data sets derived from different effector cell donors, who usually show varying donor-

dependent maximal lytic activity, were normalized. An internal positive control was set to 100 % and oa_hu225-SEED-PGLALA-mediated lysis to 0 % since this molecule is functionally inactive and reflects the tumor cell lysis induced by the NK cells alone (**Fig. 1D**). In these experiments shown in **Figure S3**, the Fc effector silenced wild-type Δ B7-H6 NK cell engager Δ B7-H6_wt SEED-PGLALA triggered significant tumor cell lysis ($EC_{50} = 1.1$ nM). Of note, all 36 Δ B7-H6 affinity-matured SEED-PGLALA molecules mediated higher maximum tumor cell lysis and achieved enhanced potency of up to 187-fold (S3#25) compared to the wild-type Δ B7-H6 immunoligand (**Fig. S3**). Among them, 11 constructs bound to NKp30 with affinity improvements of more than 10-fold ($KD < 40$ nM) and five variants comprised enhanced affinities between 5-fold and 10-fold, whereas the majority of clones comprised optimized affinities of less than 5-fold ($KD > 120$ nM; **Table I, Fig. S3**). Six of the 11 NK cell engagers constructed with the high-affinity Δ B7-H6 clones ($KD < 40$ nM), i.e. S3#14, S3#15, S3#16, S3#18, S3#24 and S3#29, induced NK cell-mediated killing of tumor cells with EC_{50} values ranging from 10.6-71.1 pM, representing a 16-fold to 106-fold increase compared to the wild-type Δ B7-H6 NK cell engager (**Fig. S3**). Of the NK cell engagers using Δ B7-H6 clones with optimized affinities for NKp30 between 5-fold and 10-fold, S3#25 and S3#31 were the most potent, displaying NKp30 affinity enhancements of 6.3-fold and 9.4-fold, respectively. These molecules induced NK cell-mediated killing of tumor cells with half-maximal killing activity of 6 pM (S3#25) and 25.1 pM (S3#31). From the variants comprising optimized NKp30 affinities of less than 5-fold, clone S3#27 ($KD = 83$ nM) elicited significant tumor cell lysis ($EC_{50} = 27.6$ pM) with 41-fold improved potency compared to wild-type Δ B7-H6 and was also selected for further characterization.

Next, the potency of the nine most active candidates from the initial screening (i.e. S3#14, S3#15, S3#16, S3#18, S3#24, S3#25, S3#27, S3#29, S3#31) was further compared via chromium release assays using A431 and A549 cells with PBMCs from 3 different donors

(**Fig. 3A**). As observed for A431 cells, the nine candidates also mediated substantially improved maximum killing and significantly enhanced potency in tumor cell lysis compared to the NK cell engager harboring wild-type Δ B7-H6 against tumor cell line A549 expressing significantly lower EGFR levels compared to A431 cells (**Fig. 3A**). While wild-type Δ B7-H6 NK cell engager Δ B7-H6_{wt} SEED-PGLALA showed significant, but limited activity (EC_{50} A431 = 1.8 nM), the most active affinity-optimized NK cell engager S3#15 demonstrated improved potency at low pM concentrations with PBMCs of 3 different donors (EC_{50} = 29.9 pM). Extent of lysis of A549 cells achieved by the most effective affinity-matured Δ B7-H6 NK cell engager S3#24 (EC_{50} = 108.3 pM), is about 3.6-times higher compared to A431 cells (**Table II**). This might most likely reflect the impact of the lower EGFR expression level on A549 target cells, a well-known parameter affecting effector cell killing. To further characterize the four most potent NK cell engagers S3#15, S3#18, S3#24 and S3#25, we performed killings assays with purified, non-stimulated NK cells (**Fig. 3B**). Using A431 cells, the four Δ B7-H6 affinity-matured NK cell engagers mediated tumor cell killing in the single digit picomolar range, representing an increase in potency of up to 87-fold (S3#15) compared to the NK cell engager harboring the wild-type Δ B7-H6 domain (**Table II**). Even for A549 target cells, potencies of all four leading hits were still in the picomolar range. Notably, efficacy of wild-type Δ B7-H6 NK cell engager was not substantially different from the negative control in NK cell ADCC with A549 cells (**Fig. 3A, B**). Finally, EGFR-specific and NKp30-mediated killing by the four leading NK cell engagers was further verified by either blocking EGFR on cell surface of A431 cells or by pre-incubation of NK cells with an excess of an anti-human NKp30 antibody. As shown in **Figure 3C**, lysis of A431 tumor cells was significantly inhibited for all four NK cell engagers under both conditions demonstrating the specificity and prerequisite of bispecific engagement of these novel B7-H6 affinity-matured immunoligands (**Fig. 3C**).

ΔB7-H6 affinity-maturated NK cell engagers exhibit a distinct NK cell activation profile

Next, we set out to scrutinize activation of NK cells in the presence of tumor cells overexpressing EGFR (A431) and the four leading immunoligands via analyzing CD69 upregulation as early NK cell activation marker. As expected, negative control (i.e. oa_hu225-SEED-PGLALA) mediated neglectable NK cell activation, whereas the NK cell engager harboring wild-type ΔB7-H6 elicited CD69 expression on approximately 17 % of NK cells on average (**Fig. 4A**). Compared to the wild-type ΔB7-H6 immunoligand, the four most potent affinity-optimized ΔB7-H6 immunoligands activated nearly twice as many NK cells ranging from 30.7 % to 33.8 % CD69-positive NK cells (**Fig. 4A**). In addition, all four leading NK cell engagers promoted significantly increased NK cell production of proinflammatory cytokines IFN-γ and TNF-α in a target-dependent manner (**Fig. 4B, C**). In comparison to the wild-type ΔB7-H6 molecule, which induced release of 141 pg/ml IFN-γ and 37 pg/ml TNF-α, S3#15, S3#18, S3#24 and S3#25 induced release of 615-824 pg/ml IFN-γ and 152-214 pg/ml TNF-α on average (**Fig. 4B, C**). Thus, affinity-engineered NK cell engagers induced up to 5.8-fold increased levels of IFN-γ and TNF-α compared to the wild-type ΔB7-H6 immunoligand. These findings are in line with the substantially enhanced killing potencies and efficacies of the affinity-engineered ΔB7-H6 NK cell engagers observed before.

ΔB7-H6 affinity-maturated NK cell engagers elucidate improved killing by concomitant engagement of FcγRIIIa

Finally, we tested the NK cell engager ΔB7-H6 S3#18, which has the highest binding affinity for NKp30 (KD = 9 nM), in the background of an Fc region capable of FcγRIIIa binding (SEEDbody lacking the L234A, L235A, P329G amino acid exchanges) to analyze whether tumor cell lysis can be further enhanced by concomitant NKp30 and FcγRIIIa activation of NK cells. The oa_hu225-SEED molecule harboring an Fc domain capable of FcR binding, but

lacking a Δ B7-H6 domain, was as potent as the affinity-matured Fc-silenced Δ B7-H6 S3#18 SEED-PGLALA molecule, which solely activates NKp30 (**Fig. 5A**). Intriguingly, incorporation of a functional Fc in the NK cell engager S3#18 (i.e. Δ B7-H6 S3#18-SEED) significantly improved half-maximal killing by 9.2-fold (**Fig. 5A**). Furthermore, as shown in **Figure 5B**, half-maximal killing achieved with Δ B7-H6 S3#18-SEED was in the range or even slightly exceeded the cytotoxic activity of the clinically applied antibody Cetuximab. These data give clear evidence that activating NK cells via NKp30 with an high affinity-engineered B7-H6-derived NK cell engager is as effective as activating NK cells via Fc γ RIIIa, and that the combination of NKp30 and Fc γ RIIIa activation of NK cells in one molecule can further potentiate the lysis of EGFR-expressing tumor cells.

Finally, we compared the capacity to trigger IFN- γ and TNF- α by the molecule engaging both NKp30 and Fc γ RIIIa with constructs engaging either NKp30 or Fc γ RIIIa and with the clinically approved antibody Cetuximab (**Fig. 5C, D**). Interestingly, the capacity to trigger cytokine release was maintained in the molecule engaging both activating receptors compared to the molecule solely engaging NKp30, with a trend towards higher TNF- α release induced by the molecule with an effector competent IgG1 backbone. Of note, compared to the therapeutic antibody Cetuximab the release of IFN- γ and TNF- α was substantially elevated, irrespective of the utilized Fc. Moreover, activation of NK cells was comparable to Cetuximab (**Fig. 5E**) Ultimately, our data demonstrate that the herein engineered NK cell engagers are capable in triggering NK cell-mediated lysis similarly effective as the clinically approved antibody Cetuximab, but in addition triggers significant IFN- γ and TNF- α release to potentially modulate anti-tumor immune responses.

Discussion

To efficiently trigger anti-tumor NK cell responses using activating NK cell engagers, the solitary *N*-terminal IgV domain of B7-H6 (Δ B7-H6) was affinity matured by a rational design and screening approach. Engineered molecules with increased NKp30 binding activity resulted in significantly improved NK cell-mediated lysis of tumor cells and enhanced secretion of proinflammatory cytokines INF- γ and TNF- α . Coligation of NKp30 and Fc γ RIIIa on NK cells further enhanced their cytotoxic activity by almost 10-fold compared to molecules engaging either receptor alone. Furthermore, the most potent novel NK cell engager was similarly effective in triggering NK cell-mediated lysis of EGFR-expressing tumor cells as the clinically approved antibody Cetuximab, but additionally promoted considerably higher release of proinflammatory cytokines. These findings suggest that the novel NK cell activating molecules may represent attractive agents to elicit strong NK cell-mediated antitumor responses.

NK cell-based therapeutic interventions represent promising approaches to improve cancer therapy by initiating a multifaceted immune response (1, 42). Since NK cell activation is tightly regulated by integrating signals of a large set of activating and inhibitory receptors (16, 17), potential therapeutic options have been proposed by either blocking inhibitory NK cell checkpoints such as NKG2A (43) or by enhancing stimulatory signals such as NKG2D, NKp30, NKp46 or the Fc γ RIIIa (23, 25, 26, 29). Since tumor cells evade NK cell recognition by down-modulation or shedding of the natural ligands of activating NK cell receptors such as MICA/B or B7-H6 (44–48), restoring NK cell recognition by enhancing surface density of activating ligands may represent a promising approach for cancer therapy. In previous studies this has been realized by fusing the natural ligands for activating NK cell receptors to scFvs or full antibodies (27–29, 38). Here, we designed novel IgG-based bispecific, multifunctional fusion proteins using the SEED technology (49) and an engineered minimal NKp30 binding domain derived from B7-H6. Since these molecules display IgG-like properties in terms of stability and

harbor an IgG Fc domain allowing FcRn binding, such molecules may show favorable characteristics compared to previously described B7-H6-based immunoligands when applied *in vivo* (50). We were able to demonstrate that the IgV domain of B7-H6 is sufficient to trigger NK cell activation. Affinity maturation of the Δ B7-H6 domain by exchanging key residues at the B7-H6/NKp30 contact interface using a combinatorial library approach resulted in significantly enhanced tumor cell lysis by NK cells. This data clearly demonstrates that similar to the Fc/Fc γ RIIIa system, which could be potently modulated by Fc-engineering, high affinity receptor engagement of NKp30 results in fundamentally improved cytotoxic response. Interestingly, also variants displaying only a moderate affinity improvement resulted in significantly increased lytic activity, which is in line with other bispecific effector cell engagers and engineered Fc domains, for which it has been demonstrated that maximal affinity enhancement may not necessarily result in improved cytolytic activity (37, 51–53). Since the observed cytolytic activity of our novel molecules does not directly correlate with binding affinity of the receptor-ligand interaction, the mechanisms of enhanced recognition might be more complex. From our experiments it could not be excluded that engineering the Δ B7-H6 domain may e.g. impact protein flexibility which in turn may have a strong impact on receptor clustering or activating synapse formation. Intriguingly, one of the best affinity-engineered Δ B7-H6 candidates triggered NK cell-mediated lysis of tumor cells via activation of NKp30 similarly effective as molecules activating Fc γ RIIIa, one of the most potent known trigger molecule on NK cells that moreover is expressed at significantly higher levels compared to NKp30 (70.000 vs 1.000 specific antigen binding sites (27)). Additionally, concomitant activation of Fc γ RIIIa and NKp30 by incorporating an effector competent IgG1 Fc backbone resulted in an almost 10-fold improved lytic capacity. This is in line with previous findings that combining monoclonal antibodies with B7-H6-based immunoligands demonstrate improved cytolytic activity (28). Moreover, Gauthier and co-workers were able to demonstrate that

simultaneous triggering of NKp46 and Fc γ RIIIa substantially enhances efficiencies of multifunctional antibodies (25). The precise underlying mechanism is not fully understood, since NKp30 and Fc γ RIIIa signal via the same adaptor chains (CD3 ζ , common γ -chain; (54)). Beyond, engagement of NKp30 via improved B7-H6-based engagers clearly differ from exclusive Fc γ RIIIa engagers in their capacity to trigger the production of pro-inflammatory cytokines. NKp30 engagers demonstrated up to 5-fold increased production of TNF- α and INF- γ compared to molecules solely triggering Fc γ RIIIa. This feature was also observed with molecules allowing concomitant NKp30 and Fc γ RIIIa engagement, indicating that Fc γ RIIIa triggering has no inhibitory effect in NKp30-mediated cytokine release. Whether this is due to distinct signaling events triggered by the two receptor systems or by activating distinct NK cell subsets must be further investigated.

Cao and colleagues demonstrated that different therapeutic treatments such as 5-FU, cisplatin, radiation and cytokine therapy with TNF- α resulted in the upregulation of B7-H6, rendering tumor cells more sensitive to NK cell-mediated killing in a NKp30-dependent fashion (55). The optimized Δ B7-H6-based agents may therefore significantly increase levels of surface-exposed B7-H6 by two different mechanisms. While obviously “artificial” decoration of tumor cells using bispecific EGFR-directed Δ B7-H6 fusion proteins results in higher surface density of Δ B7-H6, the affinity enhanced variants also significantly triggered TNF- α release by NK cells, which might in turn, as described by Cao and colleagues, lead to upregulation of endogenous B7-H6 on tumor cells in close vicinity. This might be especially interesting in situations in which the target antigen addressed by antibody-based approaches is inhomogeneously expressed, since this mechanism might sensitize tumor cells sensitive to NK cell lysis also in an antigen-independent way.

Besides TNF- α production, by triggering NKp30 the herein described immunoligands also promoted INF- γ release in a strictly targeted fashion and to a significantly larger extent than

molecules such as Cetuximab exclusively activating NK cells via FcγRIIIa. Considering the pleiotropic effects of IFN-γ (56–59) on several different immune cell subsets present in the tumor microenvironment, this may have major consequences when applied *in vivo*, especially in the treatment of solid tumors. While IFN-γ signaling has been demonstrated to promote tumor elimination by inhibiting suppressive immune cells, such as regulatory T cells (60), myeloid-derived suppressor cells (61) and tumor-associated macrophages (TAMs), IFN-γ is also critical for NK, NKT and T cell trafficking into tumors through chemokine induction (62, 63). In addition, IFN-γ activates antigen-presenting cells and cytotoxic T lymphocytes. Hence, the NK cell engagers described in this work might be able to turn *cold* tumors *hot* and may therefore represent also interesting candidates in combination with other immunomodulatory agents, such as immune checkpoint inhibitors (64, 65).

In conclusion, the herein engineered novel B7-H6-based NK cell engagers combine a unique set of effector functions to directly eliminate tumor cells by triggering NK cell cytotoxicity and eliciting a multifaceted immune reaction by promoting release of proinflammatory cytokines and therefore represent an interesting new class of immunomodulatory agents.

X-fold improvement values represent the improvement factor of respective overall affinities and off-rates against NKp30 compared to the Δ B7-H6 wild-type NK cell engager. Expression yields were determined post protein A purification. SEC indicates target monomer peaks as determined by analytical size exclusion chromatography. Mutations describes the incorporated amino acid exchanges of the variants compared to the Δ B7-H6 wild-type NK cell engager. All molecules were expressed as Fc immune effector silenced variants harboring the LALA-PG amino acid exchanges.

Table II: Potencies of selected EGFR-targeting, affinity-matured Δ B7-H6 immunoligands.

Figure 2: Affinity maturation of ΔB7-H6 by yeast surface display. (A) Co-crystal structure of ΔB7-H6 (blue) with NKp30 extracellular domain (green). Residues of ΔB7-H6 at the

interface with NKp30 and considered for focused randomization are colored in red. This illustration is based on pdb entry: 4ZSO and was generated using PyMOL v0.99. **(B)** Designated and observed amino acid distribution for specified positions of Δ B7-H6 as determined by sequencing of 96 clones. X, ambiguous. **(C)** FACS selection for the enrichment of affinity-improved variants of Δ B7-H6 by yeast surface display. A two-dimensional staining strategy for correctly displayed library candidates simultaneously binding to NKp30 was employed. 1 μ M, 100 nM and 50 nM NKp30 were used for sorting round one, two and three, respectively, to enrich high affinity binders.

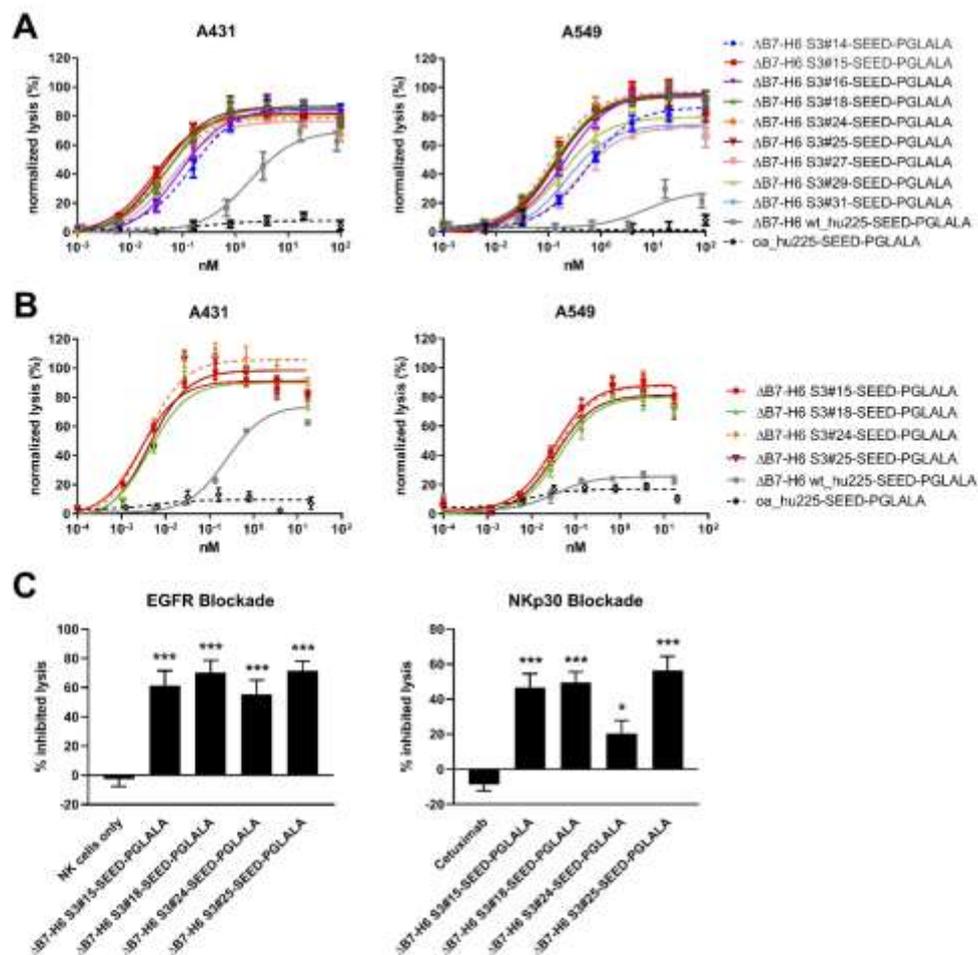

Figure 3: Cytotoxic activity of affinity-optimized Δ B7-H6-based NK cell engager. Standard 4h 51 Cr release assays were performed with A431 cells expressing high EGFR levels (left) and A549 cells expressing low EGFR levels (right) using human PBMCs at an E:T ratio of 80:1 **(A)** or purified NK cells at an E:T ratio of 10:1 **(B)** to analyze dose-dependent killing of the leading Δ B7-H6 SEED-PGLALA NK cell engager. The affinity-matured Δ B7-H6 variants were compared to wild-type Δ B7-H6 wt_hu225-SEED-PGLALA (grey) and a control molecule

lacking Δ B7-H6, but still binding one-armed (oa) to EGFR via the humanized Cetuximab Fab-fragment (oa_hu225-SEED-PGLALA; dotted black line). To allow comparison of the results, data of each experiment were normalized. Graphs show normalized means \pm SEM of three experiments performed with PBMCs or NK cell from different donors. **(C)** Specificity of A431 lysis mediated by the leading 4 NK cell engagers (applied at 0.6 nM) was verified by either blocking EGFR binding by pre-incubation of A431 cells with 50 μ g/ml of the Fc-silenced oa_hu225-SEED-PGLALA (left graph) or NKp30 binding by pre-incubation of NK cells with 50 μ g/ml anti-NKp30 antibody (right graph). Graphs show percentage of inhibited lysis as means \pm SEM of 4 individual experiments. *** $p < 0.001$; * $p < 0.05$ compared to NK cells only (left graph) or Cetuximab (right graph).

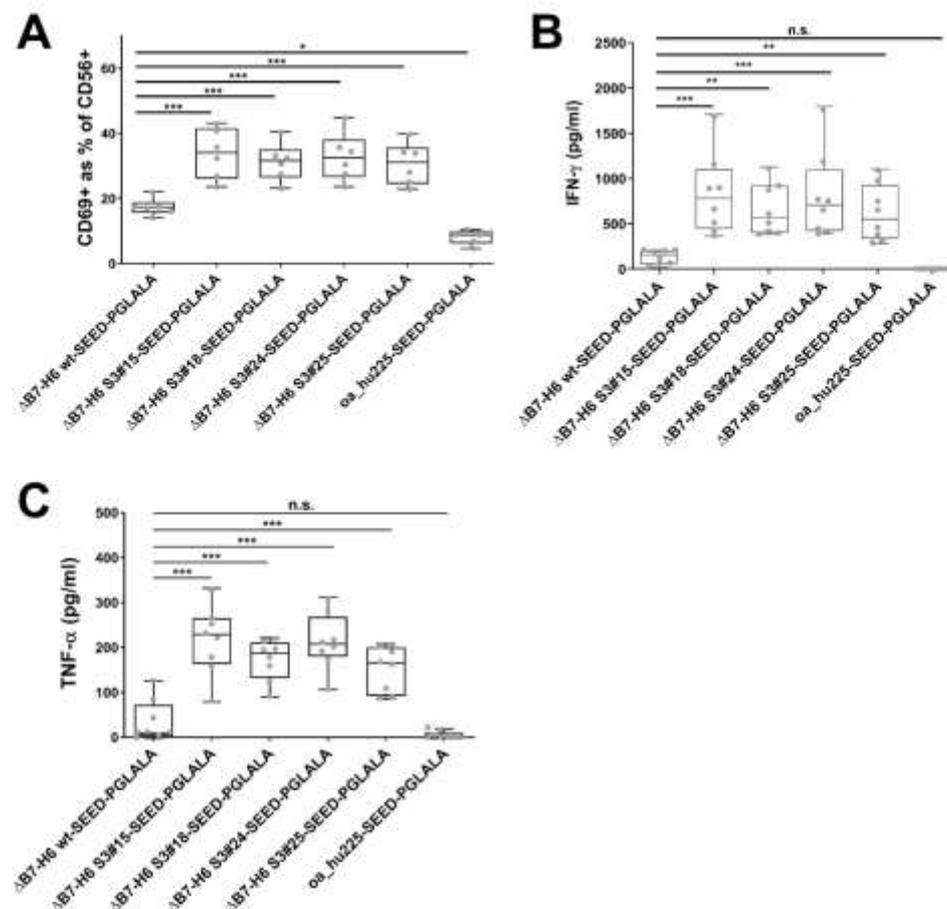

Figure 4: NK cell activation, IFN- γ and TNF- α release of the four leading Δ B7-H6 SEED-PGLALA immunoligands. Human purified NK cells were co-cultured for 24 h with A431 cells at an E:T ratio of 5:1 prior analyses of NK cell activation **(A)**, IFN- γ **(B)** and TNF- α **(C)** release. Affinity-matured Δ B7-H6 NK cell engagers and oa_hu225-SEED-PGLALA were compared to wild-type Δ B7-H6_wt-SEED-PGLALA (all at 85 nM). Percentage of CD69-positive NK cells was determined by double staining of viable NK cells with CD56-PE and

CD69-APC using flow cytometric analyses. Human cytokine HTRF kits were utilized for the quantification of IFN- γ and TNF- α release of NK cells. Graphs show box and whiskers plots as superimposition with dot plots of six (A) and eight (B, C) individual experiments, respectively. *** $p < 0.001$; ** $p < 0.01$, * $p < 0.05$, n.s. not significant compared to Δ B7-H6_wt-SEED-PGLALA.

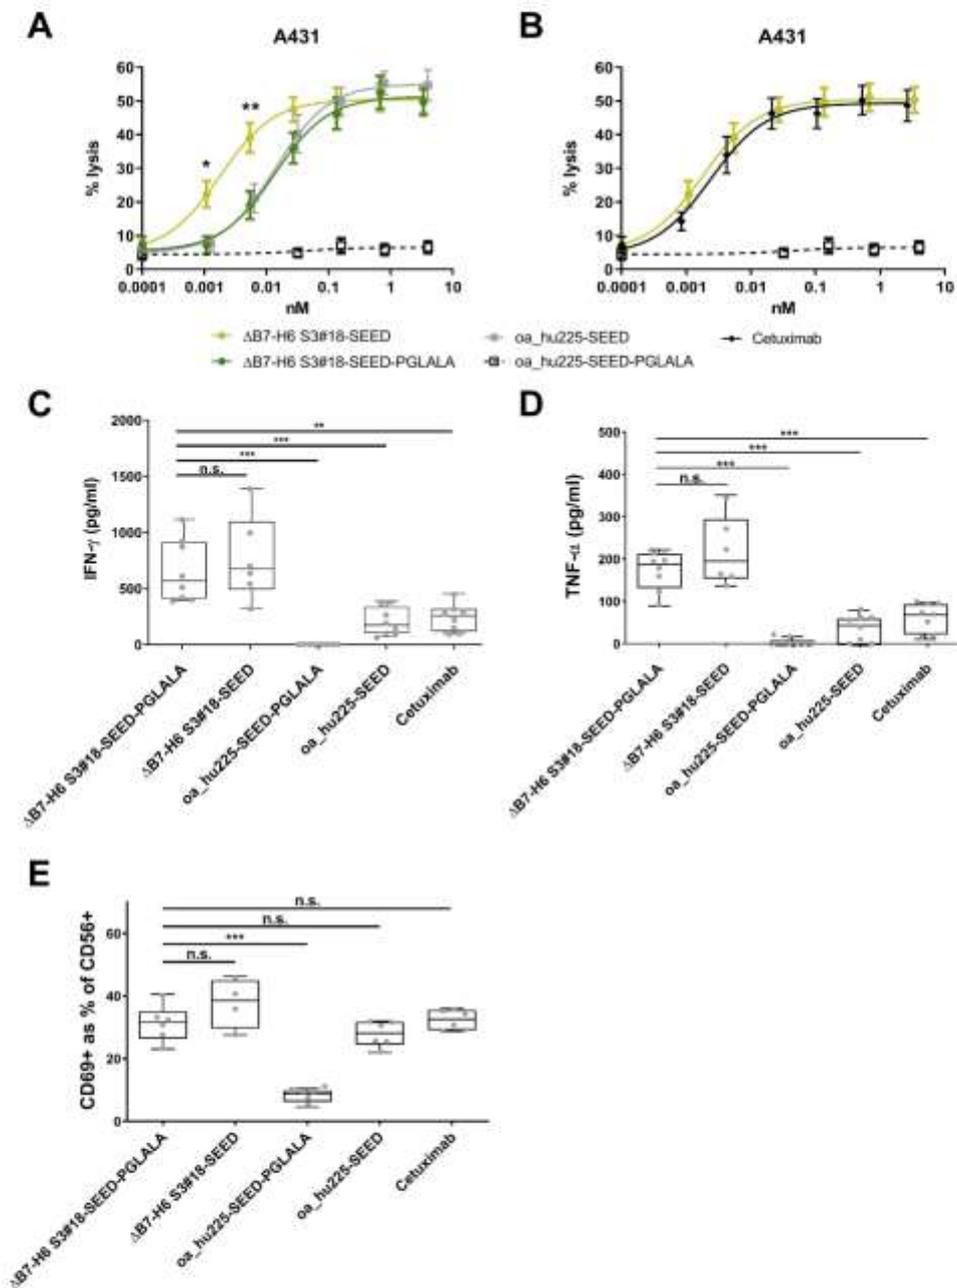

Fig. 5: Synergistic cytotoxic activity by concomitant NKp30 and FcγRIIIa engagement of ΔB7-H6-based immunoligands with functional IgG1 Fc. The highest affinity variant for NKp30 binding, S3#18, was tested in 4h ⁵¹Cr release assays with A431 cells and purified NK cells at an E:T ratio of 10:1 to compare dose-dependent killing of (A) the Fc-silenced ΔB7-H6 S3#18-SEED-PGLALA (dark green), oa_hu225-SEED (grey) lacking ΔB7-H6 and ΔB7-H6 S3#18-SEED with a functional Fc (light green) or (B) Cetuximab (black) and ΔB7-H6 S3#18 SEED both carrying a functional Fc. Fc-silenced oa_hu225-SEED-PGLALA (dotted black line) lacking also ΔB7-H6 and thus NKp30 activation was used as control. Graph shows percentage of lysis as means ± SEM of 7 independent experiments. Cytokine release of IFN-γ (C) and TNF-α (D) as well as NK cell activation (E) for effector silenced and effector competent ΔB7-H6 S3#18-SEED molecules as well as effector silenced and effector competent oa_hu225-SEED and Cetuximab (all at 85 nM). Cytokine release was analyzed after 24 h incubation of purified NK cells with A431 cells at an E:T ratio of 5:1 with human cytokine HTRF kits. Percentage of CD69-positive NK cells was determined by double staining of viable NK cells with CD56-PE and CD69-APC using flow cytometry. Human cytokine HTRF kits were utilized for the quantification of IFN-γ and TNF-α release of NK cells. Profiles show box and whiskers plots as superimpositions with dot plots of eight independent experiments. *** p < 0.001; ** p < 0.01, * p < 0.05, n.s. not significant compared to the ΔB7-H6 S3#18-SEED-PGLALA.

6.5 Antibody Display Systems

Antibodies are promising tools for biomedical applications. With respect to functionality, scientists nowadays have a plethora of options to tailor-make therapeutic antibodies with prescribed properties. Besides Hybridoma technology, which is still state-of-the-art for antibody hit discovery but that also has intrinsic limitations regarding throughput, several other promising methodologies emerged. All of these have in common that they couple the phenotype i.e. the binding properties of an antibody to its genotype, the genetic information that encodes for that particular moiety. In this chapter, the reader will learn about the most commonly applied technologies for antibody hit discovery.

11 4.1 Introduction

12 Antibodies are multifunctional components of the immune system. They facilitate numer-
13 ous cellular and humoral reactions to a plethora of different antigens. Protein-based
14 therapeutics, such as monoclonal antibodies (mAbs), have proven to be successful treat-
15 ment options for patients in various indications, e.g., in cancer. Since 1986 over 80 mAb
16 therapeutics have been granted marketing approval either in the USA or the EU [1]. In this
17 respect, one of the most successful moieties referred to as adalimumab (Humira) was
18 approved for arthritis therapy. Adalimumab is a human IgG1 with specificity for human
19 tumor necrosis factor α (TNF α) and was developed by Abbott and Cambridge Antibody
20 Technology [2]. While human antibody repertoires yield a large source for human mAbs,
21 the search for appropriate antibodies with prescribed properties during preclinical phase
22 remains laborious and challenging.

23 In general, two approaches are predominant for antibody discovery: animal immuniza-
24 tion and surface display methodologies. Since display systems can overcome the
25 limitations of animal immunizations due to a possible immune tolerance, different systems,
26 based on the in vitro selection from naïve, immunized or synthetic repertoires [3], were
27 developed over the last 30 years. Those in vitro selection platforms mimic the in vivo
28 process in B-cell lymphocytes: the generation of genotypic diversity, the coupling of
29 genotype to phenotype, application of selective pressure, and the amplification of desired
30 candidates. The first description of an in vitro display technology for the selection of
31 antibodies, namely, phage display [4], has been published in the 1990s. Since then, many
32 antibodies have been selected or optimized with the use of display methods. To this date,
33 several display systems were developed, where the polypeptide library is presented at the
34 outside of the cell wall or membrane, allowing for interaction of the library candidates with
35 the antigen. With respect to prokaryotic display systems as well as display on lower
36 eukaryotes, typically antibody derivatives are displayed as fragments such as single
37 chain Fv (scFv) or fragment antigen binding (Fab) since full length display of immuno-
38 globulin G (IgG) is rather difficult.

39 In vitro display systems can be divided into cellular and acellular approaches. Cellular
40 approaches, for example, yeast display, require the polypeptide libraries to be cloned and
41 expressed from cells, whereas in acellular approaches, for example, cDNA display, expres-
42 sion and display is accomplished without the need for transformation or transfection. Cell-

based systems rely on the multi-copy presentation of recombinant peptide libraries linked to their coding sequence on the cell surface in functional form. Repetitions of the screening and selection process with libraries of mutants enable the isolation of variants that are improved in terms of specificity and affinity. Affinities of identified antibodies in the picomolar range [5] are frequently obtained using display technologies. In contrast to the commonly applied hybridoma-technique for the generation of mAbs [6], these in vitro methods, based on microbial systems, have the possibility to automate the selection and screening process, affording the benefit of identifying a multitude of different antibody leads against a given therapeutic target. High-throughput screening allows for the selection of clones presenting an antibody variant with the desired affinity, specificity, and stability. Besides selecting antibodies against protein epitopes, display technologies also allow screening for binders recognizing chemical modifications, small molecules, toxins, and pathogens [7]. In this chapter the reader will learn about the function, applications, advantages, and limitations of the following display systems: phage, yeast, *E. coli*, mammalian, cDNA, and ribosomal display, as well as B-cell cloning.

4.2 Phage Display

Antibody phage display was the first developed and still is the most widely applied in vitro selection technology and has enabled the generation of the first fully human therapeutic antibody [2]. This platform technology has proven to be a robust and versatile methodology for the discovery of human antibodies and allows scientist to access and the rich and diverse human antibody repertoire in vitro. Phage display is based on the work of George P. Smith on filamentous *E. coli* phage M13, where Smith fused peptides to phage envelope proteins. The fusion of gene fragments of oligopeptides to the minor coat protein III gene led to genotype-phenotype coupling and consequently enabled affinity purification of the peptide and its corresponding gene (Fig. 4.1) [8]. This groundbreaking work, together with advanced applications of phage display for antibody engineering as developed by Sir Gregory P. Winter, was awarded with the Nobel Prize in Chemistry in 2018 [9]. Nowadays different phage display systems are available, most of them based on antibody::pIII fusion proteins. In this respect, integration of the antibody::pIII encoding gene into the phage genome [10] was not as successful as the commonly used phagemid system [11]. The latter has a useful and very flexible mode of action: the separation of the antibody::pIII fusion from phage protein expression, as well as phage replication. Consequently, antibody expression is uncoupled from phage propagation by keeping the genes encoding the antibody::pIII fusion proteins on a separate plasmid (called “phagemid”). This phagemid contains a phage morphogenetic signal for packing the vector into the assembled phage particles enabling coupling of the genotype (the antibody::pIII fusion) to its phenotype (antibody expression on the phage particle). However, for the production of antibody phage particles helper phage is needed [4, 11].

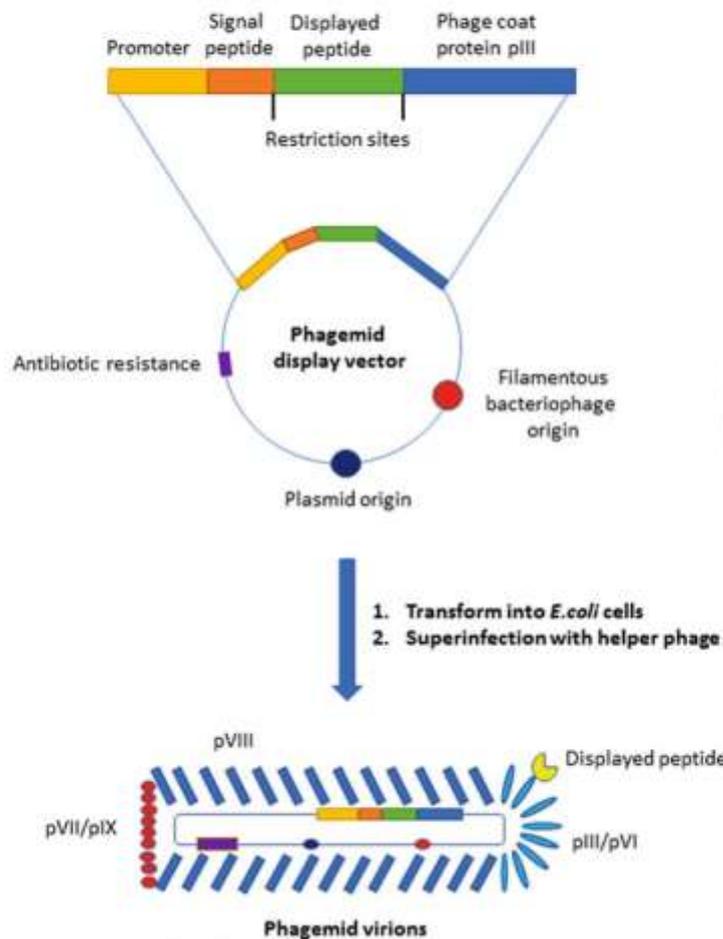

Fig. 4.1 Phage display using phagemid vectors. Typically, phagemids contain a plasmid origin of replication, a filamentous bacteriophage origin, as well as an antibiotic resistance gene for plasmid selection in *E. coli*. The library candidate is expressed as fusion protein with a phage coat protein such as pIII. A promoter enables construct expression and a signal peptide is added N-terminally. The phagemid vector is incorporated into infective phage by superinfection of phagemid bearing *E. coli* cells with helper phage. Modified from [14]

81 Inspired by the work on peptide phage display of G.P. Smith antibody phage display
 82 was developed independently in Heidelberg by Breitling and Dübel [11], in Cambridge by
 83 McCafferty et al. [10], and in California by Barbas et al. [4] Due to limitations of the *E. coli*
 84 folding machinery, only antibody fragments like scFv, Fab, the variable heavy domain of
 85 camels (VHH), or humans (dAb) are commonly used formats for antibody phage display
 86 [12]. The production of full-length IgG in *E. coli* remains challenging [13].

Essential sources for antibody discovery by phage display are antibody libraries, which can be divided into immune and universal libraries. Immune libraries are built from B-cells of immunized donors via vaccination or from patients suffering from disease. Furthermore, immune libraries can be built from samples of immunized animals, especially transgenic animals harboring the human antibody variable gene repertoire enable the selection of human antibodies without the need for a human donor. In medical research, immune libraries are used to generate an antibody against one target antigen, e.g., of an infectious pathogen [15]. Those libraries have the advantage that their V-genes contain hypermutations and are usually affinity matured. The term universal or “single-pot” libraries include naïve, semi-synthetic, and synthetic libraries. In theory, they are designed to isolate antibody fragments binding to virtually every possible antigen [16]. Naïve libraries are generated from rearranged V genes of B-cells of non-immunized donors. Semi-synthetic libraries are constructed from unrearranged V genes of germline cells or from one antibody framework in which one or several complementary determining regions (CDR), most frequently CDR-H3, are randomized [17]. Fully synthetic libraries are typically made of human frameworks with randomized CDR cassettes [18].

The first step of phage display is antibody library construction, meaning cloning of the desired antibody repertoire into the phagemid in *E. coli*. Subsequently, this *E. coli* library is infected with helper phage, providing all the necessary viral components that enable single-stranded DNA replication and packaging of the phagemid DNA into phage particles. Integration of antibody genes in phage particles leads to bacteriophages displaying the encoded antibody molecule on their outside. Consequently, the phage particle can be considered as kind of a nanoparticle displaying a distinct antibody fragment on its outside while carrying its corresponding genetic information on the inside (Fig. 4.2). The next important step to obtain a specific antibody with phage display is the “panning” process, referring to the gold washer’s tool. Therefore, a mix of billions of different bacteriophages, all displaying another antibody on their surface (in theory), is tested against one immobilized antigen molecule. The antigen can be immobilized on nitrocellulose [19], magnetic beads [20], column matrices [11], plastic surfaces like polystyrene tubes [21] or 96 well microtiter plates [4]. During this incubation step, physical (e.g., temperature), chemical (e.g., pH), and biological (e.g., competitor) parameters can be controlled. These settings enable the selection of antibodies, which can bind the antigen under these defined conditions. Due to washing steps with flexible applied stringencies, only those bacteriophages, displaying an antibody with required specificities and affinities, still bind the antigen while the others are removed by washing. After this step of enrichment, the bound and therewith desired bacteriophages can be eluted (e.g., by trypsination or pH shift) and are used to infect new *E. coli* cells enabling propagation of phagemids harboring enriched library candidates. Afterwards, those phagemid-containing *E. coli* cells are again infected with helper phage to produce new antibody phage particles (enriched for variants specific to the antigen), which can be used for further panning rounds. Normally two or three panning rounds, rarely up to six, are necessary to select antigen-binding antibody fragments. For the identification of individual binders, an antigen-binding ELISA analysis

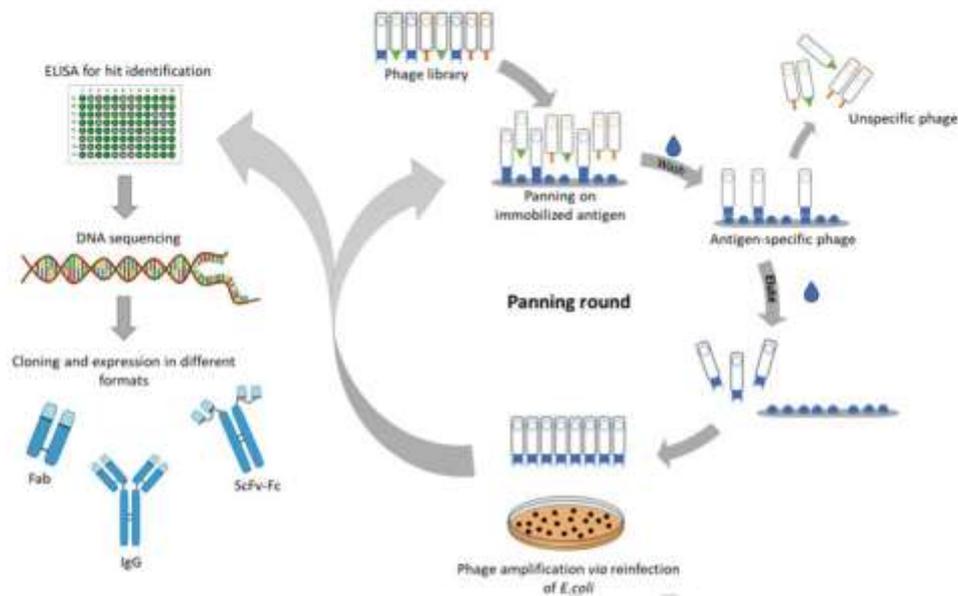

Fig. 4.2 Schematic representation of antibody phage display selection, screening, and reformatting/production. Phage library is selected for target binding, unspecific phages are removed by applying washing steps, and antigen-specific phages are eluted and amplified via reinfection of *E. coli* cells. Usually, after 2–6 panning rounds monoclonal binders are identified by ELISA, DNA-sequencing is performed and after subcloning different antibody formats can be produced. Modified from [23]

129 is commonly used. At this point it is possible to readout the genetic information through
 130 sequencing. Further biochemically characterizations can be performed. The panning pro-
 131 cess can also be performed in a high-throughput manner with automated screenings [22].

132 Initial identification of antibody candidates is often followed by an optimization step to
 133 improve affinity, stability, production yield, or other properties. Affinity maturation is an in
 134 vitro technique to evolve high-affinity ligands from polypeptide libraries. The term
 135 originates from immunology, where during a natural antibody response to an antigen, the
 136 overall affinity of circulating antibodies to the specific antigen improves. In the course of
 137 natural affinity maturation, the antibody genes of responding B-cell lymphocytes get
 138 hypermutated. Translated to antibody phage display, this means that due to gradually
 139 increasing selection stringency (e.g., decreasing antigen concentrations) only high-affinity
 140 antibodies “survive.” This principle was first demonstrated by a graduate student named
 141 Jinan Yu from the lab of George P. Smith who used an affinity maturation technique to
 142 overcome the leanness of random peptides in her starting library. She introduced random
 143 mutations into the DNA inserts during the amplification step of each round of selection. At
 144 the same time, she gradually increased stringency, similar to the decline of antigen
 145 concentrations during natural affinity maturation [24]. The successful outcome of an
 146 affinity maturation campaign is a so-called “dark horse” peptide: a peptide with higher

affinity to the antigen compared to all the other clones, which have evolved from the initial peptide ancestor [25]. Another commonly used strategy is the so called light-chain-shuffling, which combines the heavy chains of a panned subset of antibodies with the whole light-chain repertoire of a naïve or synthetic library [26]. This newly generated library is then re-screened under modified conditions to obtain antibodies with improved properties.

Today the typical task of antibody research facilities is to generate antibodies to many different antigens in a high-throughput manner requiring minimal effort. To compete here, automation and miniaturization are essential. With the use of deep-screening, nowadays, one can typically analyze more than 20,000 individual clones, often resulting in more than 100 different binders. A huge improvement of efficiency was the development of hyperphage, a helper phage significantly enhancing antibody display efficiency [27]. This very elegant approach developed by Stefan Dübel and co-workers has been nicely described elsewhere [27].

At present, multiple phage display-derived mAbs are in clinical or preclinical stages of development, with several antibodies that have been granted marketing access either in the USA or the EU. The most successful phage display-derived mAbs are described in the following paragraph.

Adalimumab (marketed as Humira) was the first phage display-derived monoclonal antibody approved for therapy. It is used as a TNF-inhibiting anti-inflammatory drug and is approved by the FDA for treatment of rheumatoid arthritis, juvenile idiopathic arthritis, psoriatic arthritis, ankylosing spondylitis, Crohn's disease, ulcerative colitis, and plaque psoriasis [28–30]. In 2011 the phage display-derived antibody Belimumab, which inhibits B-cell-activating factor, was approved by the FDA. It is used for treatment of autoimmune diseases, mainly systemic lupus erythematosus [31]. Ranibizumab, FDA approved in 2006, is an antibody against VEGF-A and neutralizes its activity. The antibody was affinity matured by phage display and is used for treatment of wet age-related macular edema [32]. Another human mAb, generated with the use of phage display, was FDA approved in the year 2012: Raxibacumab, an antibody binding to the protective antigen (PA83) of *Bacillus anthracis*. Nowadays Raxibacumab is used for treatment of inhalational anthrax raised from *B. anthracis* in combination with antibacterial drugs [33]. In addition to the four herein described phage display-derived mAbs, two more (Necitumumab and Ramucirumab) entities were approved by the US authorities as of May 2016, and a plethora of antibodies is currently undergoing clinical evaluation, clearly demonstrating the versatility of phage display for antibody selection in terms of disease therapy [23].

4.3 Yeast Surface Display

The in vitro selection of human antibody fragment libraries displayed on yeast surfaces represents a well-established technology capable of generating target-specific mAbs. The most commonly used species in this strategy is *Saccharomyces cerevisiae*. This eukaryotic

186 organism normally uses its cell wall surface agglutinins as adhesion proteins for instance
187 during mating events [34]. Yeast surface display (YSD) is based on the genetic fusion of an
188 antibody fragment to such cell wall proteins, e.g., to Aga2p, as developed by Boder and
189 Wittrup in 1997 [35, 36]. In this well-established system employing mating-related
190 proteins Aga1p and Aga2p, the Aga2p subunit, to which the protein of interest is fused,
191 is covalently linked to the yeast cell wall via two disulfide bonds to Aga1p [37]. The
192 subunit Aga1p contains the glycosylphosphatidylinositol (GPI) anchor and consequently is
193 responsible for cell wall anchoring, whereas Aga2p acts as interaction module with Aga1p
194 [38] (Fig. 4.3).

195 The first step to construct yeast antibody display libraries relies in the cloning of the
196 immunoglobulin gene pool into the yeast display plasmid [39–42] as fusion to the gene
197 encoding for Aga2p. Using this platform technology libraries in the range of 10^7 to 10^9 ,
198 unique variants can readily be obtained [37, 43]. In the most established system developed
199 by Boder and Wittrup, the expression of both Aga1p (integrated into the yeast genome) and
200 the mAb-Aga2p fusion construct (expressed from the display plasmid) is under the control
201 of the galactose-inducible GAL1 promoter. The presence of galactose as carbon source
202 (instead of glucose) enables the yeast cells to display the antibody fragment fused to Aga2p
203 subunit on their surface [43, 44]. ScFv is the most commonly used antibody format in yeast
204 display; however Fabs [45], whole IgG1s, and camelid antibodies [46] can be displayed as
205 well [44].

206 It's been known quite well that YSD enables the obtain antigen-specific antibodies [47].
207 Isolation of antibody clones from yeast libraries can be performed using magnetic-assisted
208 cell sorting (MACS) and fluorescence-activated cell sorting (FACS) [43]. MACS steps are
209 typically used to remove nonbinding mAb fragments to reduce the number of cells for
210 subsequent FACS selection, since throughput is the limiting factor for the latter. These
211 MACS separations are comparable with the phage panning process and can reduce the
212 nonreactive background by approximately 100 times [44]. After MACS-based depletion,
213 the antigen-enriched population of yeast cells is screened by FACS in order to isolate
214 antigen-specific library candidates (Fig. 4.4). The antigen concentration during FACS
215 screening is often kept at tenfold excess above the desired dissociation constant (K_D) of
216 individual clones to allow the majority of the displayed mAb fragments to bind the target at
217 equilibrium. Implementation of epitope tags, for instance, a hemagglutinin (HA) tag or a c-
218 myc epitope at the termini of the respective library candidate allow for immunofluorescent
219 detection of full-length proteins that are displayed on the surface of the yeast cell. This is
220 advantageous since it allows for getting rid of frame-shifted library candidates or
221 candidates containing stop codons. Both malfunctioned versions of library candidates
222 typically have a tendency for aggregation as well as unspecific binding which would result
223 in false-positive events. The screened yeast cells are labeled for the simultaneous detection
224 of antibody fragment expression, i.e., display on the cell surface (using, e.g., the c-myc tag)
225 and antigen binding (using a fluorescence label on the target). During the first FACS
226 selection round, typically the complete double-positive population is collected in order to
227 enrich the complete antigen-specific diversity. In subsequent FACS rounds, the selection

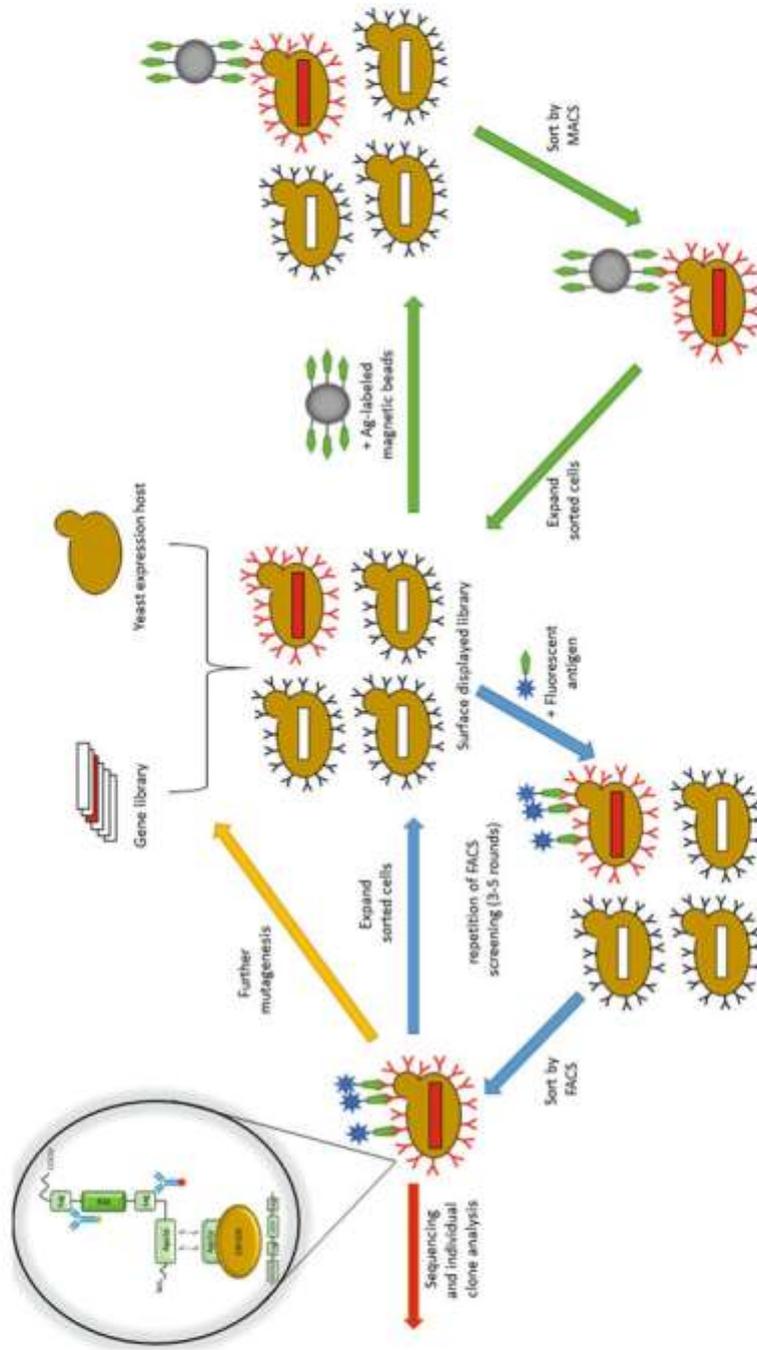

Fig. 4.3 Schematic representation of yeast display and yeast display library selection. In yeast display, the protein of interest (POI) is expressed as fusion protein with Aga2p, which upon secretion forms a covalent linkage with Aga1p that is situated on the cell surface. Tags can be included for the detection of full-length display and the POI can be fused N- or C-terminally to Aga2p. GOI, gene of interest. After library construction, the yeast display library can be either selected by MACS using antigen-coated magnetic beads or by FACS using fluorescently-labeled antigen. After a particular selection round, enriched cells are expanded and subsequently utilized for further rounds of selection. Typically, after 3–5 FACS-based selections, individual plasmids are analyzed by sequencing. Moreover, antigen-enriched cells can be further modified by mutagenesis. Modified from [44, 48]

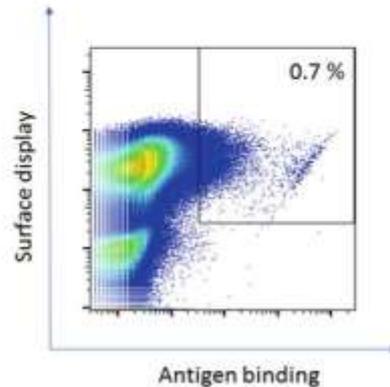

Fig. 4.4 Exemplary blot showing first round of selection of a single domain antibody library constructed from immunized camelids against a given target. The Y-axis indicates full-length surface display by antibody-mediated fluorescence labeling of a tag that has been included in plasmid design and the X-axis represents antigen binding (using a fluorescently labeled antigen). By applying a sorting gate, the double-positive population can be sorted

228 gate can then be adjusted to increase sorting stringency [43]. Typically, after three to five
 229 rounds of these FACS selections, the plasmid DNA of the enriched antigen binding
 230 population is collected and sent out for sequencing to obtain the genetic information for
 231 the respective paratopes. These can further be subcloned into appropriate plasmids
 232 enabling antibody expression in mammalian cells.

233 When comparing yeast and phage antibody library technologies, both advantages and
 234 disadvantages exist. A big advantage of yeast display is the precise control over selection
 235 parameters during FACS screening [47]. This ability to prescribe binding criteria during the
 236 FACS process represents an advantage over phage display platforms, where variant
 237 discrimination is dependent on washing steps rather than real-time kinetic observations
 238 [44]. Moreover, due to the utilization of a eukaryotic expression host with proper quality
 239 control machineries, proteins are believed to be more properly folded compared to phage
 240 display, where a prokaryotic expression host is employed [44]. However, compared to
 241 phage display, there are also some obvious drawbacks. Total library sizes using yeast
 242 libraries tend to be significantly lower (several orders of magnitude) than typical phage
 243 display library sizes. The reason therefore relies in lower transformation efficiencies
 244 observed in yeast cells. While yeast libraries with up to 10^{10} total clones can be constructed
 245 with a reasonable effort, phage libraries with more than 10^{11} variants can readily be
 246 obtained [43, 49]. Another potential disadvantage of YSD is the high number of antibody
 247 copies displayed per cell (ranges between 10^4 and 10^5 copies per cell), leading to a
 248 selection based on antibody avidity, rather than affinity (at least in theory. However, this
 249 is not true by all means, as shown in the next paragraph). Modern selection strategies make
 250 use of both yeast and phage display in combinatorial approaches. The two-system strategy
 251 takes advantage of the strengths of both technologies: the large library size and affinity-

based selections of phage display and the well-controlled isolation of variants from yeast display [50].

A conventional application of YSD is affinity maturation of antibody fragments. Wittrup and co-workers were able to demonstrate the effectiveness of YSD in protein affinity maturation with their studies on an anti-fluorescein scFv in 1997 [36]. Flow cytometry allows for the detection as well as quantification of the fluorescence signal from each yeast cell [36]. This feature allows for precise affinity measurements and rapid enrichment of high-affinity populations within mutant libraries [36, 51]. These mutant libraries are often screened with a limiting concentration of soluble antigen to select mutants having higher affinities. In this way Boder et al. developed an antibody with affinity among the highest reported so far ($K_D = 48$ fM) [51]. Chao et al. gave a detailed methodical protocol for affinity engineering by YSD [43]. They described the use of random mutagenesis through error-prone PCR, enabling the control of mutation frequencies by varying the number of PCR cycles [43]. Other methodologies of generating diversity, such as DNA shuffling [52], are also compatible with YSD. Besides affinity maturation of antibodies, the feasibility of this approach has been extended to T-cell receptors [53, 54]. Moreover, YSD can also be used for epitope mapping of antibodies [55].

A more recent application of YSD are cell-based selections. Shusta et al. showed that yeast cells displaying high-affinity single-chain T-cell receptors (scTCRs) can build a cell-cell complex with an antigen presenting cell (APC) [56]. These results give clear evidence that the YSD can be used to screen yeast polypeptide libraries against cell surface ligands. Indeed, several reports show that such cell-based selection can be effectively performed. In this respect Wang et al. identified 34 unique antibodies binding and in some cases internalizing into rat brain endothelial cells [57]. Cell-based selections enable the identification of antibodies against complex membrane proteins, avoiding the requirement for sophisticated and difficult membrane protein expression and purification.

As of January 2020, one yeast display-derived mAb was approved by the Chinese authorities. This antibody, referred to as Sintilimab, is a fully human therapeutic entity blocking the interaction of PD-1 to PD-L1 and PD-L2 [58].

4.4 Mammalian Display

Phage display and yeast display enable the isolation of antigen-specific antibodies with desired functionalities. However, essential intrinsic properties that qualify an antibody to become a potential therapeutic such as high-level expression in mammalian cells, aggregation behavior, or accurate glycosylation (that might impact immunogenicity) can only insufficiently be controlled using microbial display technologies. To address these characteristics more adequately, mammalian-based selection systems have been developed. In this section, we aim at giving the reader an overview of some of the key principles of this selection strategy.

290 Mammalian cell display systems can be broadly categorized into methods employing
291 transient protein candidate expression and those taking advantage of stable cell lines.
292 Transient expression is a very effective way for short-term expression of proteins. Yet, it
293 results in loss of overall DNA within the course of a few days and consequently to
294 inefficient mid-term and long-term expression. Typically, such transient expression
295 systems are utilized for a single round of selection followed by plasmid rescue. In contrast
296 to this, stable integration would result in constant mid-term (and long-term) expression of
297 library candidates. Nevertheless, stable integration is a relatively rare event and such
298 systems are commonly used the construction of rather small libraries. Selection from
299 large libraries using stably integrated gene expression used to be extremely inefficient
300 [59]. With the event of modern technologies of genetic engineering and gene editing,
301 however, huge progress has been in this respect during the last years.

302 Higuchi and colleagues were one of the first groups developing methods for mammalian
303 antibody display (Fig. 4.5). They constructed a novel screening system, which allows to
304 obtain variable region (V) genes of antigen-specific antibodies using mammalian cells as an
305 expression host. To this end, they displayed an antibody library on the surface of COS cells
306 by utilization of a plasmid allowing for expression of membrane-bound antibodies. In more
307 detail, the first step was library generation, which was prepared from peripheral blood
308 lymphocytes of a human donor vaccinated against hepatitis B surface antigen (HBsAg).
309 mRNA extraction and cDNA synthesis were performed, followed by gene amplification of
310 antibody variable regions via PCR and cloning into a display vector. Afterwards COS7
311 cells were transiently transfected. Membrane-anchoring was achieved by *in frame* genetic
312 fusion of the antibody variant to the transmembrane domain of human thrombomodulin.
313 The generated combinatorial library had a size of approximately 5×10^6 independent
314 clones. In order to select for antigen-specific antibodies, the COS library was stained with
315 biotin-labeled antigen and sorted by flow cytometry. Afterwards, plasmids were extracted
316 from antigen-enriched cells followed by re-amplification in *E. coli* and repetition of the
317 whole process for three rounds. Overall, this led to a 450-fold enrichment of V genes
318 coding for HBsAg-specific antibodies. Finally, variable region genes were isolated and
319 inserted into an expression allowing for soluble antibody expression, resulting ultimately
320 into the isolation of four unique clones specific for HBsAg [60].

321 In recent years, several different technologies for mammalian display emerged. In 2009
322 Ho and Pastan showed that human embryonic kidney cells (HEK293T) can be used for
323 surface display of scFvs and affinity maturation of those [61]. Moreover, Zhou et al.
324 described the presentation of full-length antibodies on the surface of CHO cells by applying
325 the Flp-In technology (Invitrogen). In this approach, recombinase-mediated chromosomal
326 (stable) DNA integration was used to generate library diversity, and antibodies with
327 significantly improved neutralizing activity and affinities could be isolated [62].

328 Retrocyte display, a technique where the natural expression apparatus of B-cells is
329 exploited for retroviral B lymphocyte display, was developed in 2014 [63]. Here, libraries
330 in the range of 10^9 clones were generated by step-wise transduction of immortalized pre-B-
331 cells with retroviral particles carrying light chain and heavy chain diversities, respectively.

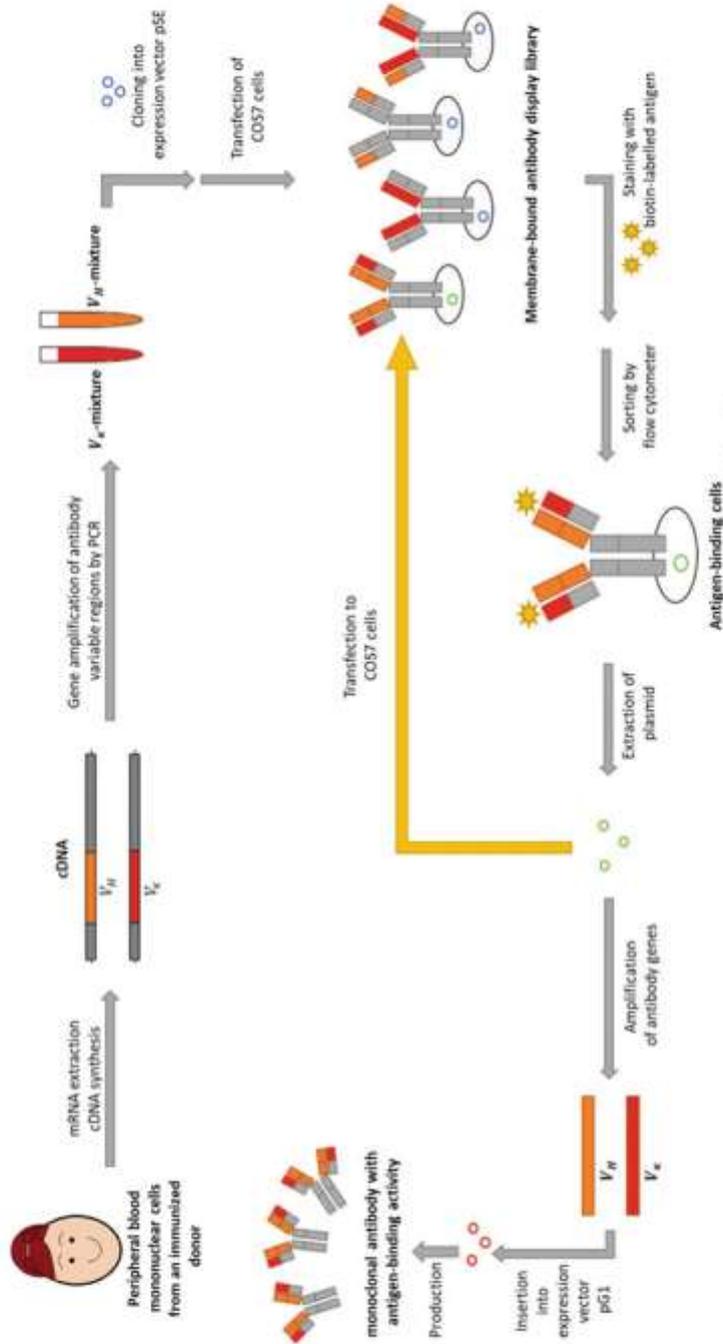

Fig. 4.5 Scheme of the preparation of a cell display library and the selection of antigen-specific antibody V genes by FACS. Messenger RNA was extracted from peripheral blood mononuclear cells of an immunized human donor. Antibody V genes were obtained from mRNA by RT-PCR and inserted into expression vector pSE. A cell display library was prepared by transfecting COS7 cells with the resultant plasmids. The library was stained with biotin-conjugated antigen followed by PE-conjugated streptavidin, and then positively stained cells were sorted by flow cytometry. Plasmids containing antigen-specific antibody V genes were recovered from the collected cells, and this enrichment process was repeated several times. Antigen-specific antibody V genes were isolated from the finally obtained plasmids and inserted into expression vector pG1 to produce monoclonal antibodies with antigen-binding activity. Modified from [60]

332 Besides remarkable library sizes for mammalian display, this technology is supposed to
333 have the advantage of enhanced antibody display efficacy. This is due to the utilization of
334 naturally antibody producing B-lineage cells with the presence of all necessary co-factors
335 that ensure proper protein folding, antibody heavy-light chain assembly, glycosylation, and
336 disulfide bridge formation. Besides, Beerli and co-workers described a mammalian display
337 system relying on a Sindbis virus expression system [64]. Another technology employing
338 viral components for mammalian display is referred to as vaccinia virus display. This virus
339 infects most mammalian cell lines, leading to expression of recombinant genes with
340 mammalian quality control and post-translational modification [65]. In this approach,
341 mammalian cells were co-transduced with an antibody heavy chain library and an addi-
342 tional light chain library. Interestingly, the heavy chain was produced as a fusion with a
343 vaccinia virus membrane protein. Consequently, the full-length antibody was not only
344 expressed on the surface of the infected cell but also on the surface of the virus particle shed
345 from the cell. Similar to phage display, this allows for “panning” of huge diversities and
346 enrichment of antigen-specific clones. Subsequently, infected mammalian cells can be
347 sorted by FACS enabling precise control over selection. Besides viral transduction in the
348 context of mammalian display, libraries can also be generated using non-viral transposition
349 technology [66].

350 Another fascinating system of mammalian display was described by Bowers et al. [67].
351 Essentially, this method makes use of the enzyme named activation-induced cytidine
352 deaminase (AID) that is responsible for the initiation of the natural affinity maturation
353 process in B-cells, which is referred to as somatic hypermutation [67]. In a first step, low
354 affinity antibodies were selected against a given target and assessed for functionality.
355 Subsequently, genes for antigen-positive antibodies were co-transfected with AID into
356 HEK293 cells allowing for simultaneous display and affinity maturation. Ultimately, this
357 enabled the isolation of high-affinity antibodies. Another approach focusing on a natural
358 diversification mechanism of antibody repertoires was presented in 2005 by Ohta and co-
359 workers [68]. Here, the authors utilized a chicken B-cell line for antibody diversification. In
360 chickens, antibody diversity is generated in a process called gene conversion, a kind of
361 homologous recombination. By treating the chicken B-cell line with a histone deacetylase
362 inhibitor, the gene conversion frequency increased massively, resulting in a diversity at the
363 immunoglobulin locus sufficient for the selection of antigen-specific antibodies. Other
364 approaches employ CRISPR/Cas9 or TALE nucleases as tools for library construction as
365 well as for homology-directed mutagenesis [69, 70].

366 In addition to the selection and affinity maturation of antigen-specific antibodies,
367 mammalian display systems can also be utilized for the selection of functional, e.g.,
368 agonistic or antagonistic antibodies. In 2012 Lerner et al. published a new lentiviral
369 screening method that allowed for the selection for erythropoietin agonistic antibodies.
370 The authors first enriched antibodies specific to EpoR via phage display, followed by
371 lentiviral library preparation. Afterwards, reporter cells were transduced with the pre-
372 enriched lentiviral library and the phenotype, i.e., function of the antibodies was monitored

[71]. The authors further demonstrated the applicability of their studies by appropriate reporter cell engineering and by optimizing the autocrine selection system itself [72].

4.5 *E. coli* Display

Besides the often cumbersome application of eukaryotic systems, the use of prokaryotic *Escherichia coli* cells for the cell surface display of heterologous peptides offers a facile and rapid alternative. The availability of numerous genetic tools, mutant strains, and the high transformation efficiencies of *E. coli* makes it an attractive host for screening large peptide libraries. Microbial cell-surface display has many potential applications, e.g., live vaccine development, peptide library screening, antibody production in animals, bioconversion using whole cell biocatalysts, biosensor development, and bioadsorption [73]. To this end, the protein of interest to be presented, referred to as passenger protein, can be fused by N-terminal, C-terminal, or sandwich fusion to the surface anchor, the so-called carrier protein. The utilized fusion arrangement, as well as the characteristics of the carrier protein, passenger protein, and the host cell strain, affects the efficiency of surface display regarding immobilization yield, stability, specific activity, and post-translational modification of the fusion protein [73].

Unfortunately, there is no microbial equivalent of the glycosylphosphatidylinositol (GPI) anchor found in eukaryotic cells for facile display of heterologous proteins in prokaryotic cells. Thus, the carrier protein must be adjusted for each passenger protein as well as for each individual application to enable adequate transport through the inner membrane. Moreover, the carrier protein should be unsusceptible for protease degradation, anchor the passenger protein reliable to the membrane, and utilize the fusion or insertion of foreign peptide sequences and therefore their proper orientation and surface presentation [73, 74].

Based on those requirements and the complex cell envelope of gram negative bacteria such as *E. coli*, most carrier proteins developed to date are based on the outer membrane proteins (Fig. 4.6), supporting the accessibility of the passenger protein [74]. These proteins comprise a plethora of different molecules, e.g., bacterial fimbriae, S-layer proteins, ice nucleation protein (INP) [75–78], protein peptidoglycan-associated lipoprotein (PAL) [79], members of the immunoglobulin A (IgA) protease family [80], *Shigella* outer membrane autotransporter protein (IcsA/VirG), and many others more (Fig. 4.6).

Combining the appropriate fusion profile with a suitable carrier protein is therefore essential for microbial surface display.

Jose et al. demonstrated, for example, the surface presentation of *Vibrio cholerae* toxin B subunit (CtxB) as a heterologous passenger via N-terminal fusion to the β domain of IgA protease which mediates the translocation due autotransporter function [80]. Another example for the N-terminal fusion arrangement was the display of alkaline phosphatase (PhoA) and maltose-binding protein (MalE) by the group of Sasakawa [81] via *Shigella* VirG protein, which is important for the deposition of filamentous actin.

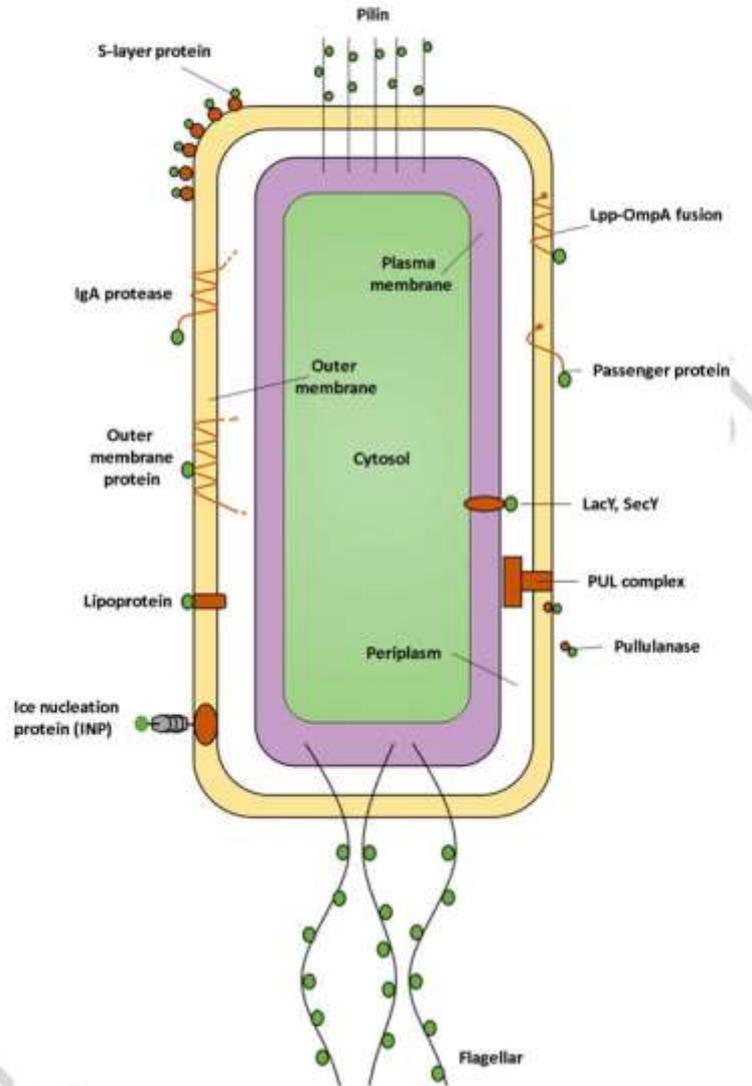

Fig. 4.6 Different surface display systems developed in Gram-negative bacteria; Modified from [73]

412 In contrast to that, the Lpp-OmpA-hybrid carrier system is an example for a mechanism
 413 constructed with the C-terminal fusion method. It takes advantage of the signal sequence
 414 and the first N-terminal residues of the mature *E. coli* lipoprotein and residues of the *E. coli*
 415 outer membrane protein A (OmpA). Lpp is responsible for the adequate translocation of
 416 the fusion protein in the periplasm, whereas OmpA is necessary for crossing the outer
 417 membrane [82–85].

Despite N-terminal and C-terminal fusion, sandwich arrangement is a suitable strategy for the surface display of peptides on Gram-negative bacteria using whole structure proteins. The lack of anchoring regions does not allow for the truncation of these outer membrane proteins (OMPs), subunit proteins of extracellular extensions, and S-layer proteins (Fig. 4.6). For example, OmpC forms a transmembrane β -barrel structure spanning the outer membrane and allowing its external loops to be used as fusion sites, as shown in 1999 by Zhaohui Xu and Sang Yup Lee [74]. More recently, Bessette et al. developed a system based on a surface-exposed loop of *E. coli* OmpA allowing rapid isolation of high-affinity protein-binding peptides. Using sequential MACS and FACS analysis, proteins with high binding affinities (K_D in the low nanomolar range) for a variety of distinct antigens (e.g., streptavidin and HIV-1 GPI20) could be isolated straightforward [86].

One of the major drawbacks of the microbial display system was the difficulty in presenting complex structures such as antibodies.

In 2008 Georgiou and colleagues addressed this issue by bacterial periplasmic display of so-called E-clonal mAbs [87]. Therefore, antibody heavy and light chains were secreted into the periplasm of *E. coli*, where they were properly folded and assembled into aglycosylated IgGs. The antibody immobilization on the inner membrane facing the periplasm was mediated by a chimeric NlpA-ZZ fusion protein. Permeabilization of the outer membrane resulted in spheroplast clones that could be screened via FACS for specific antigen binding.

Another approach of microbial antibody display was published in 2015 by Wang and colleagues. They were able to present the neutralizing single-chain antibody VRC01 against HIV-1 infection on *E. coli* cells and showed that the engineered bacterial cells could capture HIV-1 particles and inhibit HIV-1 infection in cell culture [88]. Furthermore, in 2016 the group of Fernández isolated human fibrinogen nanobodies (VHHs) using *E. coli* display by fusing an immune library of VHH domains to the β -domain of intimin [89, 90].

As mentioned before, bacterial display systems are interesting for the development of recombinant bacterial vaccines. They consist of an avirulent bacterial or viral carrier expressing foreign passenger antigens. Bacteria, e.g., *E. coli*, are attractive candidates as carriers, because they are often strongly immunogenic and capable of colonizing host tissues. Another advantage of bacterial vaccines is their ability to express various foreign antigens in different forms (e.g., soluble, membrane bound, secreted). Moreover, surface-exposed antigens may facilitate the recognition by the immune system with bacterial lipopolysaccharides (LPS) acting as immune-adjuvants due to their immunogenicity [91]. This approach was already used in 1987 by Charbit et al. to display foreign epitopes of hepatitis B virus surface antigen on *E. coli*. Intravenous injections into rabbits and mice resulted in high titer specific antibody responses indicating a decent immune response [92]. In addition, Agterberg and colleagues immunized guinea pigs with partially purified outer membrane pore protein E (PhoE) carrying inserted epitopes from foot-and-mouth disease virus, which yielded substantial titers of neutralizing antibodies, protecting the guinea pigs completely against challenge with the virus [93].

460 4.6 Ribosome Display

461 A representative of the next generation of display technologies is ribosome display, which
462 may overcome some limitations of cell-based display strategies by using a cell-free
463 expression system.

464 One limitation of conventional cellular systems is the host's transformation efficiency,
465 which can limit the overall number of library variants.

466 During ribosome display, genotype phenotype coupling is mediated by the formation of
467 ternary antibody-ribosome-mRNA (ARM) complexes in cell extracts, without the require-
468 ment of transformation steps. The absence of a stop-codon on the mRNA leads to a stalling
469 of the ribosome at the end of translation. The release of the polypeptide chain cannot be
470 triggered by release factors that normally take the place of the tRNA at that position.

471 Thereby the individual protein of interest (e.g., an antibody fragment) is connected to its
472 corresponding mRNA, which enables the simultaneous isolation of the functional protein
473 and its encoding mRNA (genotype-phenotype coupling). ARM complexes are stabilized
474 by high concentrations of magnesium ions and low temperature for several days [94].
475 Selection steps are performed through affinity capture with a specific ligand, e.g., bound on
476 magnetic beads. Afterwards the mRNA is recovered as DNA by reverse transcription (RT)-
477 PCR. Successive screening rounds allow the isolation of high-affinity antibodies. Both
478 prokaryotic and eukaryotic ribosome display systems have been developed (Fig. 4.7) [95,
479 96].

480 The biggest advantage of ribosome display over phage display and cell surface display
481 systems is the possibility to generate and screen larger libraries. As uncloned PCR
482 fragments are utilized as source of diversity, libraries with 10^{12-14} members can easily be
483 produced [97]. Restrictions are the number of functional ribosomes as well as the presence
484 of different mRNA molecules in the reaction.

485 In addition, uncloned PCR fragments can be easily used to introduce new diversity
486 during selection [98, 99]. For example, non-proofreading polymerases [100], error-prone
487 PCR, DNase I shuffling [101, 102] and amplification of templates by PCR in the presence
488 of dNTP-analogs such as 8-oxo-guanosine or dPTP [103] are convenient methods for
489 diversification of the repertoire. This capability of continuously diversifying DNA
490 followed by selection against an antigen provides an optimal system for in vitro antibody
491 maturation and directed evolution of binding proteins [104, 105].

492 At last, ribosome display is also suited to display proteins that are difficult or impossible
493 to express by cell-based systems, since cell-free systems tolerate also toxic, proteolytically
494 sensitive, or unstable proteins.

495 In the following, the different types of ribosome display systems (*E. coli* S30 system,
496 eukaryotic systems, and wheat germ system) will be described. In the first publication of
497 ribosome display, the *E. coli* S30 system was utilized for peptide selection (Fig. 4.7). The
498 so-called polysome display generates polysome complexes (stalled Ribosome/mRNA
499 complexes) with chloramphenicol [106]. The isolation of polysome complexes displaying
500 interacting peptide epitopes was performed by capture with an immobilized antibody on

4 Antibody Display Systems

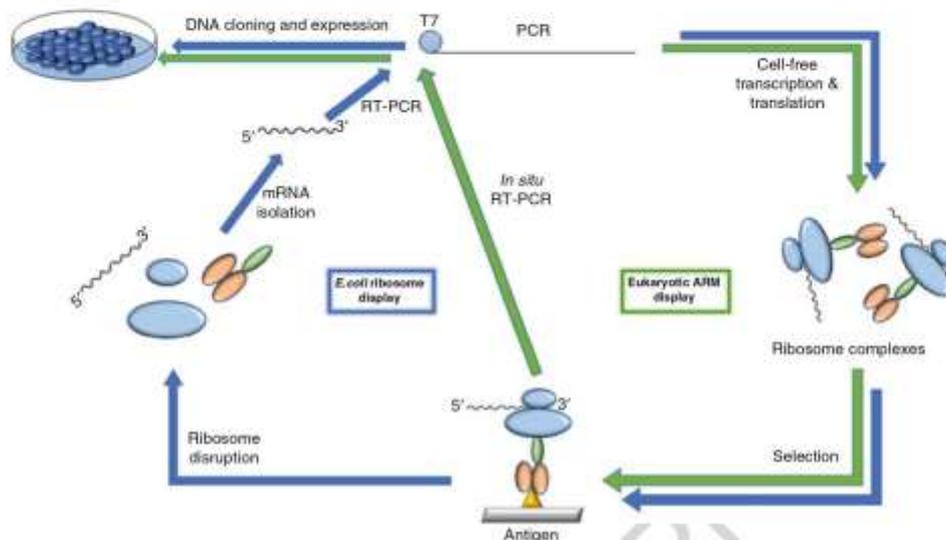

Fig. 4.7 Ribosome display cycles. *E. coli* ribosome display cycle (left side in blue) and eukaryotic ARM display cycle (right side in green). RT: reverse transcription, T7: T7 promoter, ARM: antibody-ribosome-mRNA. Modified from [95]

microtiter wells. The dissociation of the complexes was accomplished by EDTA to release 501
the bound mRNA. Afterwards DNA recovery was performed by RT-PCR. To display 502
single-chain antibody fragments, the system was later modified by Hanes and colleagues. 503
They generated ARM complexes through deletion of the 3' terminal stop codon from DNA 504
[107]. In 2004, Sawata et al. further refined the *E. coli* S30 system by introducing a protein- 505
mRNA interaction to generate even more stable ribosome complexes, leading to an 506
improved selection efficiency [108]. 507

In the meantime, a eukaryotic ribosome display system was developed for selection of 508
single-chain antibody fragments. The coupled rabbit reticulocyte lysate system was 509
initially termed "ARM display" (Fig. 4.7) [109]. This system also utilized the deletion of 510
the stop codon from the DNA to generate eukaryotic ribosome complexes. A novel 511
recovery procedure was developed, in which RT-PCR was performed directly on the 512
ribosome complexes without the dissociation step used in former systems. For this, in 513
situ RT-PCR primers were designed, which hybridize slightly upstream of the mRNA 3' 514
end, thereby preventing binding to the ribosome-covered region [109]. In situ RT-PCR 515
facilitates automation of the entire ribosome display process. 516

The procedure was later modified by inclusion of oxidized/reduced glutathione and Q β 517
RNA-dependent RNA polymerase for improvement of protein folding and introduction of 518
mutations [110]. 519

Kanamori and colleagues developed a highly controllable ribosome display using the 520
PURE (Protein synthesis Using Recombinant Elements) system in the year 2014. Herein, 521

522 ARM complexes are highly stable, and the selected mRNA can easily be recovered,
523 because of very low nuclease activity combined with reconstitution of components such
524 as ribosome and translation factors [111]. In 2002, a wheat germ cell-free protein synthesis
525 system has also been developed for ribosome display of folded proteins [112].

526 There are some key factors affecting ribosome display, which are mentioned below.
527 Constructs for ribosome display require a promoter such as T7 and a translation initiation
528 sequence (Shine-Dalgarno for *E. coli* S30 system or Kozak sequence for eukaryotic
529 systems). Furthermore, a linker of at least 23–30 amino acids in length is required at the
530 proteins C-terminus. This generates a spacer between the ribosome and the displayed
531 protein and abolishes steric hindrance [96]. In addition, a sequence for the hybridization
532 of primers in RT-PCR recovery stage, as well as the incorporation of sequences containing
533 stem-loop structures at both ends of the DNA to stabilize mRNA against degradation, is
534 required [106]. The choice of a cell-free system may affect the formation of ribosome
535 complexes either as monoribosome or polysome complexes, which can carry more than
536 one ribosome translating a single mRNA molecule and can lead to avidity effects. Rabbit
537 reticulocyte lysate can produce mainly monoribosome complexes, whereas *E. coli* S30
538 usually generates polysomes [95, 106]. Furthermore, cell-free systems can be divided into
539 coupled (simpler and more efficient) and uncoupled systems. In a coupled system, tran-
540 scription of the DNA template is immediately followed by translation. An uncoupled
541 system translates mRNA, which is generated either by in vitro transcription or isolated
542 from native sources. It allows the optimization of the transcription and translation step
543 separately.

544 Ribosome display systems have been successfully applied for in vitro antibody selec-
545 tion, evolution, and humanization. Repeated rounds of mutation and selection led to the
546 isolation of antibody variants with improved affinity, specificity, and stability [94, 96, 98,
547 113]. In 2006, Groves and colleagues could show that ribosome display is suited for
548 affinity maturation of phage display-derived antibody populations. In addition, they com-
549 pared the output of phage and ribosome display which were able to demonstrate that higher
550 affinity antibodies were isolated using ribosome display [114].

AU4

551 4.7 cDNA Display

552 After the development of ribosome display [107] (described above) and mRNA display
553 [115], in which the protein of interest is linked to its coding mRNA via a puromycin-linker
554 (Pu-linker), the cDNA display technology was developed utilizing a similar strategy (Fig.
555 4.8). cDNA display is a powerful in vitro display technology in which complementary
556 DNA is fused to its coding peptide or protein via a covalent puromycin linkage [116]. The
557 technology is used to explore functional peptides and proteins from huge libraries by in
558 vitro selection. In contrast to mRNA display, where a puromycin molecule is covalently
559 linked to the mRNA via a DNA spacer, in cDNA display, the DNA is directly fused to the
560 C-terminus of the peptide or protein via puromycin. This makes cDNA display more stable

4 Antibody Display Systems

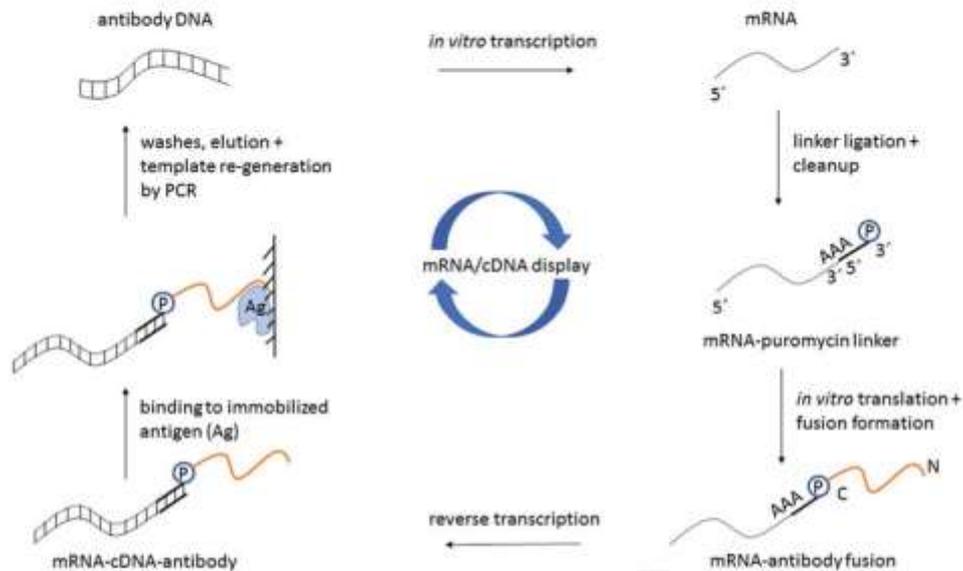

Fig. 4.8 Schematic for mRNA/cDNA display of antibodies. Antibody-encoding DNA is in vitro transcribed to mRNA and ligated to a 3' puromycin (P) containing DNA linker. Following in vitro translation and fusion formation, reverse transcription is performed to synthesize cDNA. mRNA-cDNA-antibody complexes are exposed to the antigen (Ag) of interest, which is immobilized on a solid-phase affinity matrix. Following washes and elution, PCR is performed to retrieve antibody-encoding amplicons. N/C: N- and C-termini of displayed antibody. Modified from [118]

compared to other in vitro selection methods. Besides others, cDNA display was used for selection of peptide-based affinity reagents against cell surface proteins. For example, peptides binding to G protein-coupled receptors (GPCRs) could be selected, using cells with high GPCR expression [117].

cDNA display was further refined during the last years, especially the Pu-linker technology. Mochizuki, Ueno, and colleagues could improve the preparation efficiency of the cDNA display complex by developing additional Pu-linkers [119, 120] and modifying the preparation protocol [121]. These modifications make cDNA display more practical. The novel Pu-linker, developed by the same group., contains 3-cyanovinylcarbazole nucleoside (cnvK) and is called the cnvK-Pu-linker. cnvK is an ultrafast photo-cross-linker using UV irradiation to connect hybridized oligonucleotides, which enables ultrafast cross-linking without the use of an enzymatic ligation reaction [122]. Furthermore, cDNA display can be used as screening method for functional disulfide-rich peptides by solid-phase synthesis, promoting protein folding. Yamaguchi and colleagues could select novel peptides against the interleukin-6 receptor, containing multiple disulfide bonds [116].

576 4.8 B-Cell Cloning

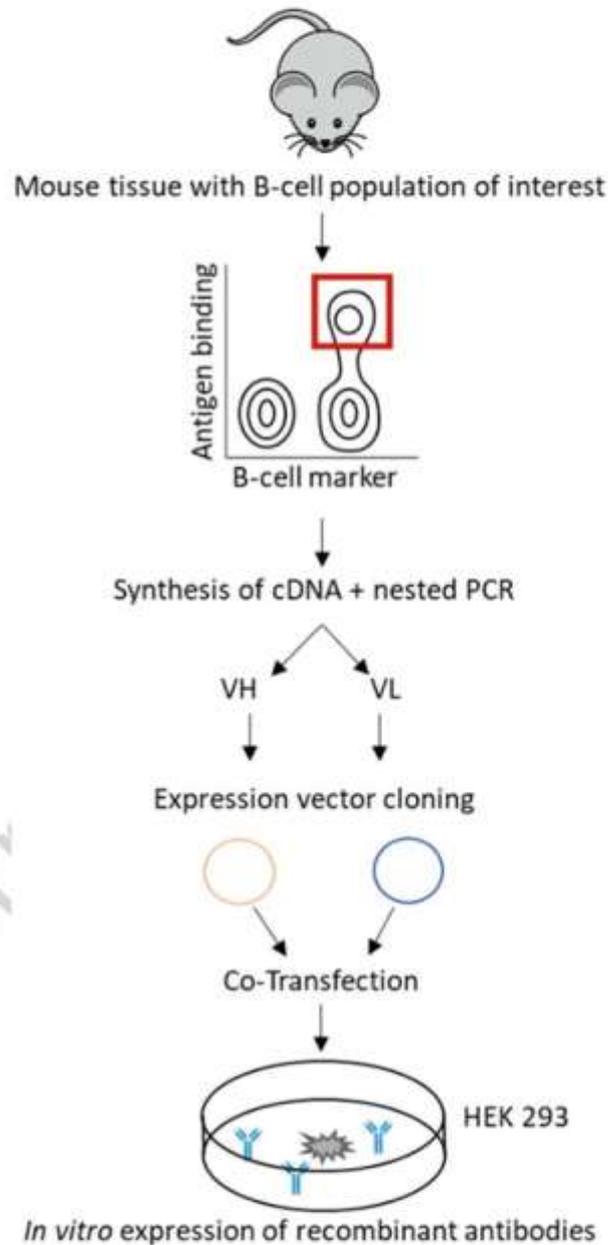

577 Similar to hybridoma technology, single B-cell technologies retain the natural heavy and
578 light chain pairing of immunized B-cells. However, in contrast to hybridoma that has the
579 disadvantage of low fusion efficacies resulting in inadequate diversity sampling and the
580 potential loss of rare but specific antibodies, an efficient mining of the immunized B-cell
581 population is enabled by single cell B-cell cloning [123, 124]. Generally, this platform
582 technology comprises of several consecutive steps, i.e., detection of (antigen-specific) B-
583 cells within a population of different cells (e.g., splenocytes, lymphocytes, or PBMCs),
584 amplification of the variable regions of the heavy chain and the light chain from selected
585 single B-cells, cloning into expression vectors, antibody production, and characterization
586 (Fig. 4.9). Single B-cell isolation can either be performed randomly (i.e., without selecting
587 for antigen specificity) or in an antigen-selective manner. Techniques for the isolation of B
588 cells in randomly comprise but are not limited to cell picking by micromanipulation [125],
589 laser capture microdissection, [126] and FACS [127, 128]. Alternatively, single B-cell
590 isolation in an antigen-selective manner has been described with the use of antigen-coated
591 magnetic beads [129], fluorochrome-labeled antigens via multi-parameter FACS [130], the
592 hemolytic plaque assay, [131] and a fluorescent foci method [132]. One of the most
593 commonly applied techniques for the isolation of antigen-specific B-cells is fluorescence-
594 activated cell sorting. Here, a multi-parameter labeling strategy is typically employed: On
595 the one hand, fluorescently labeled antibodies against surface markers of B-cells (such as
596 CD19) are utilized to gate for the specific B-cell population within the tissue sample. On the
597 other hand, a fluorescently labeled antigen allows for the isolation of antigen-positive B
598 cells. Single B-cell technologies have been elegantly reviewed by Rashidian and Lloyd
599 [133].

600 Tiller et al. developed a highly efficient strategy to generate monoclonal antibodies from
601 human B-cells at different stages of development based on surface marker expression
602 [128]. Antibodies targeting different surface markers of B-cells and labeled with different
603 fluorescence dyes allowed to discriminate between subpopulations of B-cells at different
604 stages of development. A nested RT-PCR approach on sorted B-cells allowed for the
605 amplification of heavy chain as well as light chain variable regions, followed by cloning
606 into appropriate expression plasmids, antibody production, and characterization.

607 Starkie and co-workers described an efficient strategy for the isolation of antigen-
608 specific antibodies from immunized mice [123]. Here, B-cells from the spleen were first
609 enriched by MACS using anti-mouse CD45R microbeads. Afterwards, a multi-parameter
610 staining strategy involving fluorescently labeled antibodies targeting different mouse
611 isotypes such as IgG, IgM, and IgD as well as antibodies targeting different surface markers
612 of desired (B-cell) and undesired (e.g., T-cell) populations enabled the isolation of antigen-
613 specific class-switched IgG-positive memory B-cells.

614 In 2017, Carbonetti et al. described an efficient mAb discovery platform that combines
615 single B-cell selection as well as B-cell cultivation [135]. Initially, after immunization of
616 mice, spleens were harvested, homogenized to single cell suspension, and MACS was

Fig. 4.9 Schematic representation of the B-cell cloning technology from immunized mice. Single B-cells isolated from mouse tissues are sorted by FACS. After reverse transcription, VH and VL genes are amplified from sorted single B-cell cDNA in independent PCRs. Subsequently, variable regions are cloned into expression vectors comprising constant antibody regions. For production of monoclonal antibodies, expression vectors can be co-transfected into mammalian cells such as HEK 293. Modified from [134]

employed for the enrichment of B-cell populations. A multi-parameter labeling strategy 617
 was further applied for FACS-based sorting of antigen-positive cells. Subsequently, 618
 isolated B-cells were co-cultured with CD40L-positive feeder cells as well as supportive 619
 cytokines for the induction of proliferation and mAb production. Antibody-containing 620

621 supernatants were then assessed with respect to reactivity. Afterwards, positive cells were
622 harvested for RNA isolation, variable gene amplification, cloning, and antibody
623 expression.

624 Besides the selection of antigen-specific B-cells using different methodologies with
625 varying levels of complexities [136–140], also methods for the selection of mAbs from
626 plasma cells have been described. Plasma cells are differentiated B-cells that secrete
627 antibodies (in fact, they are responsible for producing immunoglobulins in the blood
628 circulation). However, plasma cells normally do not express the antibody moiety on their
629 surface, a fact that makes the isolation of antigen-specific plasma cells rather complicated.
630 In this respect, Lightwood and co-workers described a method referred to as fluorescent
631 foci method [141]. This fluorescence-based system was performed on microscope slides
632 with the use of a micromanipulator device for isolation of antigen-specific IgG secreting
633 cells. Here, IgG-secreting cells were mixed with a solid phase antigen as well as with a
634 FITC-labeled anti-Fc γ -specific antibody and plated as a monolayer on glass slides. Anti-
635 gen-specific plasma cells secreting the desired antibody were visualized through the
636 formation of a FITC-based halo surrounding the cell. This is because the secreted specific
637 antibodies bind the antigen in the direct surrounding of the antigen-specific plasma cell,
638 allowing for labeling with the Fc γ -targeting detection moiety.

639 Recent progress in microfluidic systems enabled new strategies in single-cell technol-
640 ogy with significant advantages in terms of phenotypic screenings for antibodies with
641 desired properties (e.g., total assay volumes in a small range allowing to obtain detectable
642 concentrations of secreted antibodies from single cells). Nowadays, reactions can be
643 compartmentalized in droplets surrounded by oil or air. The droplets typically shaped in
644 a very uniform size (typically between 10 and 200 μm in diameter) contain all assay
645 reagents needed as well as a single cell to be characterized. In this way thousands of
646 individual compartments can be generated per second. The generated droplets can be sorted
647 according to fluorescence signals in an automated fashion via fluorescence-activated
648 droplet sorting (FADS), enabling phenotypic screening of hundreds of samples per second.
649 The technology overcomes the need for any slow mechanical equipment such as
650 micromanipulators. Furthermore, the approach should also be applicable to non-
651 immortalized primary B-cells, because no cell proliferation is required. In addition to the
652 phenotypic screens, next-generation sequencing (NGS)-based approaches can be exploited
653 to gather information about antibody binding. Those approaches are called “Ig-seq” [142].
654 DeKosky and colleagues developed an entirely emulsion-based technology, where single
655 B-cells were encapsulated in water-in-oil droplets. The technology allowed the sequencing
656 of repertoires of more than 2×10^6 B-cells in a single experiment [143]. In the near to mid-
657 term future, microfluidics might ultimately allow to screen B-cells from humans to generate
658 highly specific therapeutics. Screenings will become more efficient by the use of highly
659 advanced devices for single cell manipulation, which can be rapidly automated and
660 remotely controlled. In this respect, several services and devices from different companies
661 are available [124, 144, 145].

4.9 Take Home Message

662

- Antibody display systems enable the identification of antibodies with prescribed properties from huge repertoires. 663 664
- The key feature that facilitates the selection of a favored library candidate relies in coupling the phenotype (i.e., the antibody protein) to its genotype (i.e., the DNA encoding for the entity). 665 666 667
- The most frequently used technology is phage display that enabled the generation or isolation of multiple marketed antibody derivatives. 668 669
- Yeast surface display emerged as another platform technology that has proven to be successful for antibody hit discovery and engineering. 670 671
- In recent years several different mammalian display systems were developed that make use of higher eukaryotic quality control machineries. 672 673
- B-cell cloning can be considered as the most natural form of genotype phenotype coupling utilizing the native protein production and secretion apparatus of antibody producing cells. 674 675 676

Chapter 10

Isolation of Antigen-Specific VHH Single-Domain Antibodies by Combining Animal Immunization with Yeast Surface Display

Lukas Roth, Simon Krah, Janina Klemm, Ralf Günther, Lars Toleikis, Michael Busch, Stefan Becker, and Stefan Zielonka

Abstract

In addition to conventional hetero-tetrameric antibodies, the adaptive immune repertoire of camelids comprises the so-called heavy chain-only antibodies devoid of light chains. Consequently, antigen binding is mediated solely by the variable domain of the heavy chain, referred to as VHH. In recent years, these single-domain moieties emerged as promising tools for biotechnological and biomedical applications. In this chapter, we describe the generation of VHH antibody yeast surface display libraries from immunized Alpacas and Lamas as well as the facile isolation of antigen-specific molecules in a convenient fluorescence-activated cell sorting (FACS)-based selection process.

Key words Yeast surface display, Antibody engineering, Protein engineering, Camelid antibodies, Single-domain antibodies, VHH (variable domain of the heavy chain of heavy chain-only antibodies)

1 Introduction

From a structural aspect, conventional antibodies are homodimers of heavy- and light-chain heterodimers (Fig. 1). The antigen binding site, i.e., paratope is formed by the variable domain of the heavy chain and the variable domain of the light chain. In addition to this, it's been known for quite some time that camelids and sharks produce heavy chain-only antibodies (HcAbs) [1, 2]. Such molecules are homodimeric by nature since they are composed of two heavy chains and lack light chain counterparts. Moreover, with respect to camelid-derived heavy chain-only antibodies the first constant domain CH1 that typically interacts with the constant region of the light chain is absent in these moieties (Fig. 1). Interestingly, HcAbs specifically recognize an antigen with only one variable domain, referred to as variable domain of the heavy chain of heavy chain-only antibodies (VHH) for camelid-derived

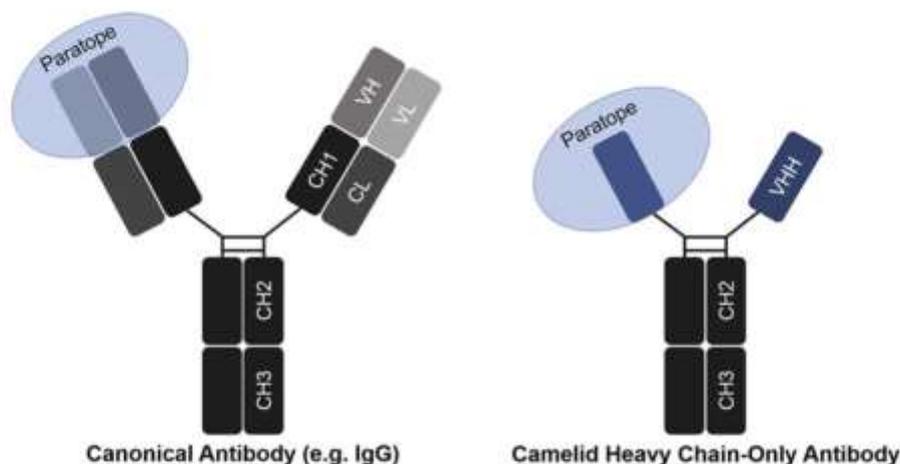

Fig. 1 Structural illustration of conventional hetero-tetrameric antibodies (left) and camelid-derived heavy chain-only antibodies

molecules [3]. This VHH domain displays several attributes making it interesting for biomedical and biotechnological applications. In this respect, complementarity determining region 3 (CDR3) is typically elongated compared to conventional antibodies [4]. This protruding loop enables engagement of epitopes that are typically not antigenic to canonical antibodies, i.e., cryptic or recessed epitopes such as catalytic clefts [5–7]. Besides, also the hypervariable region, corresponding to CDR1, is extended by four residues at the N-terminal end and is likely involved in antigen binding [3]. Moreover, camelid VHH domains are generally highly water soluble. This is due to replacements of large and hydrophobic residues by small and hydrophilic amino acids in framework region-2 that normally builds the interaction surface with the variable domain of the light chain [8, 9]. Furthermore, the surface-exposed loop of CDR3 is often connected with CDR1 or CDR2 via an additional disulfide bond [4, 10]. However, also CDR3 intraloop disulfides have been described for VHHs [11]. Camelid VHH domains share a high sequence similarity with human VH domains [3]. Notwithstanding, to reduce the potential for immunogenicity, a general strategy for humanization has been presented by Vincke and colleagues [12].

Due to their simple architecture, camelid VHH domains afford the benefit of flexible reformatting options, including bi- and multispecific constructs opening new avenues for targeting diseases [13–16]. Consequently, a plethora of different strategies have been described for the generation of antigen-specific VHH fragments, including naïve, semi-synthetic, synthetic, and immunized library approaches [17–22], and several VHH-derived molecules are currently investigated in clinical trials [4, 10, 23].

Although the vast majority of engineered VHH domains were obtained using phage display as platform technology [20, 24], it has been shown that such antigen-specific single-domain antibodies can readily be isolated using yeast surface display (YSD) [25]. Pioneered by Boder and Wittrup in 1997 [26], this genotype-phenotype coupling technology relies on the expression of the protein of interest as fusion with Aga2p mating adhesion receptor of *Saccharomyces cerevisiae*. Surface display is enabled through covalent linkage of Aga2p to Aga1p that is anchored to the cell wall. One of the major benefits of YSD is the utilization of a eukaryotic expression system comprising unfolded protein response for the degradation of misfolded or aggregated proteins [27]. Moreover, its compatibility with fluorescence-activated cell sorting (FACS) enables online and real-time analysis of individual library candidates [28].

In this chapter, we provide protocols for facile VHH library construction following Alpaca and Lama immunization as well as for the isolation of antigen-specific molecules using a FACS-based selection strategy. To this end, VHH genes are amplified from PBMC-derived cDNA in a one-step PCR and introduced into a yeast surface display vector in a homologous recombination-based process referred to as gap repair cloning. By application of a two-dimensional sorting strategy for the detection of full-length surface display as well as antigen binding, we show that target-specific VHHs can readily be obtained within two rounds of FACS selections.

2 Materials

2.1 Strains

1. *Saccharomyces cerevisiae* strain EBY100 (MATa) (URA3-52 trp1 leu2 Δ 1 his3 Δ 200 pep4::HIS3 prb1 Δ 1.6R can1 GAL) (pIU211:URA3).
2. *E. coli* strain Top10 (F-*mcrA* Δ (*mrr-bsdRMS-mcrBC*) Φ 80*lacZ* Δ M15 Δ *lacX74* *recA1* *araD139* Δ (*ara leu*) 7697 *galU galK rpsL* (StrR) *endA1 nupG*).

2.2 Plasmids

Substantial features of display plasmid are schematically shown in Fig. 2. A pYD-derived backbone is used as destination vector (pDest) containing essential features, i.e., tryptophan auxotrophic marker for selection in EBY100, ampicillin resistance marker (AmpR) for selection in *E. coli*, GAL1 promoter and replication origins in *S. cerevisiae* (ARS4/CEN6) and *E. coli* (ColE1), and terminator sequences (not shown). The coding VHH region is genetically fused *in frame* to Aga2p by replacement of stuffer sequence after pDest digestion with *BsaI* and gap repair cloning. Therefore, the VHH gene is flanked by homologous overhangs to

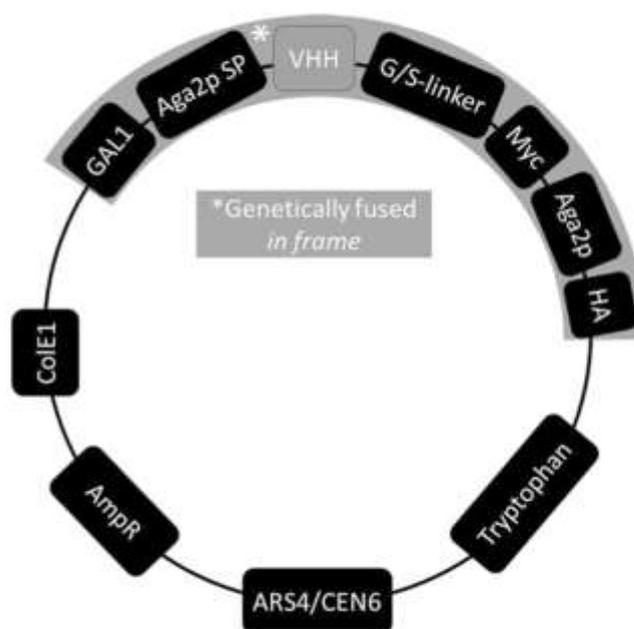

Fig. 2 Schematic illustration of generated yeast surface display plasmid. Main genetic components of the system are shown. GAL1, GAL1 promoter; Aga2 SP, Aga2 signal peptide; VHH, camelid variable domain of the heavy chain of heavy chain-only antibodies; G/S-linker, glycine-serine linker; Myc, Myc epitope; Aga2p, Aga2p cell adhesion molecule; HA, HA-tag; tryptophan, tryptophan auxotrophic marker; ARS4/CEN6, replication origin for yeast; AmpR, ampicillin resistance marker; ColE1, replication origin for *E. coli*. Illustrated features from GAL1 to HA were genetically fused in frame on the used plasmid

G/S linker as well as Aga2p signal sequence (*see Note 1*) facilitating homologous recombination (Fig. 3). A HA-tag is linked to Aga2p allowing for the detection of VHH surface expression.

2.3 Media

1. YPD media: Dissolve 20 g D(+)-glucose, 20 g peptone, and 10 g yeast extract in 1 l deionized H₂O. Sterilize by autoclaving. Add 10 ml of Penicillin–Streptomycin (10,000 units/ml) and remove any particles by sterile filtration using a 0.22 μm bottle top filter.
2. SD-Trp media: Dissolve 26.7 g minimal SD-Base (Clontech) in deionized H₂O and adjust volume to 890 ml. Sterilize by autoclaving. Dissolve 8.56 g NaH₂PO₄ × H₂O, 5.4 g Na₂HPO₄, and 0.74 g Dropout-mix -Trp (Clontech) in deionized H₂O and adjust the volume to 100 ml. Sterilize by autoclaving. Combine both solutions, add 10 ml of Penicillin–Streptomycin (Gibco, 10,000 units/ml), and remove any particles by sterile filtration using a 0.22 μm bottle top filter.

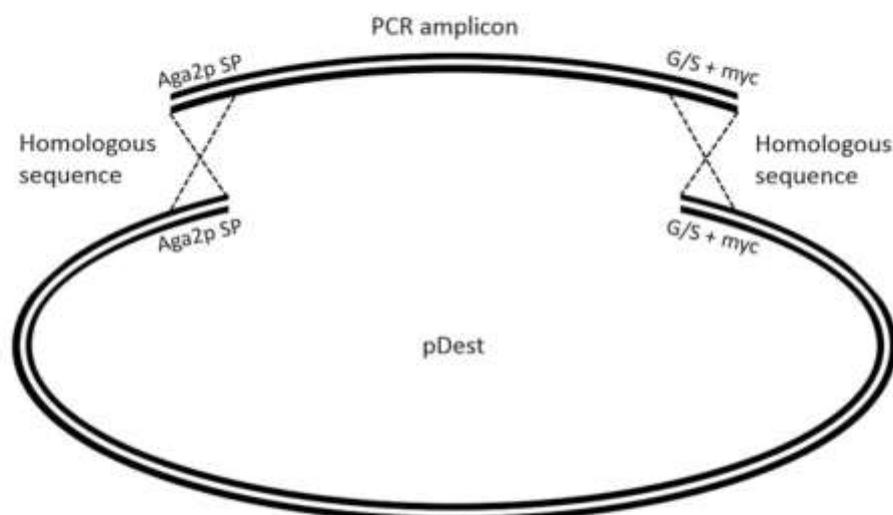

Fig. 3 Gap repair cloning scheme for generation of yeast surface display antibody libraries by homologous recombination. Restriction enzyme digested destination plasmid (pDest) and PCR amplicons with homologous overhangs are shown. Homologous regions are embedded in Aga2p signal peptide sequence and G/S-linker with joined myc-tag, respectively, facilitating homologous recombination to generate the final display plasmid

3. SD-Trp plates: Dissolve 23.35 g of minimal SD-Agar Base (Clontech) in deionized H₂O and adjust volume to 445 ml. Sterilize by autoclaving. Dissolve 4.28 g of NaH₂PO₄ × H₂O, 2.7 g of Na₂HPO₄, and 0.37 g Dropout-mix -Trp in deionized H₂O and adjust the volume to 50 ml. Sterilize by autoclaving. Combine both solutions, add 10 ml of Penicillin–Streptomycin (Gibco, 10,000 units/ml), and prepare plates.
4. SG -Trp media: Dissolve 37 g of minimal SD-Base + Gal/Raf in deionized H₂O and adjust volume to 490 ml. Dissolve 8.56 g of NaH₂PO₄ × H₂O, 5.4 g of Na₂HPO₄, and 0.74 g Dropout-mix -Trp in deionized H₂O and adjust the volume to 100 ml. Dissolve 110 g of PEG8000 in deionized H₂O and adjust the volume to 400 ml. Sterilize by autoclaving and combine all three solutions. Add 10 ml of Penicillin–Streptomycin (10,000 units/ml) and remove any particles by sterile filtration using a 0.22 μm bottle top filter.
5. SD Low -Trp medium: Dissolve 5 g dextrose, 6.7 g yeast nitrogen base (w/o amino acids) in deionized H₂O, and adjust volume to 890 ml. Sterilize by autoclaving. Dissolve 8.56 g NaH₂PO₄ × H₂O, 5.4 g Na₂HPO₄ and 0.74 g Dropout-mix -Trp in deionized H₂O and adjust the volume to 100 ml. Sterilize by autoclaving. Combine both solutions, add 10 ml of Penicillin–Streptomycin (10,000 units/ml), and remove any particles by sterile filtration using a 0.22 μm bottle top filter.

6. Yeast library freezing solution: Dissolve 2 g of glycerol and 0.67 g of yeast nitrogen base in a volume of 100 ml deionized H₂O. Sterile filter the solution.
7. LB Amp media: Dissolve 10 g NaCl, 10 g peptone, and 5 g yeast extract in 1 l deionized water. Sterilize by autoclaving. Once the medium has chilled (to approximately 50 °C), add 1 ml of sterile filtered ampicillin solution (100 mg/ml in deionized H₂O).
8. LB Amp plates: Dissolve 10 g NaCl, 10 g peptone, 5 g yeast extract, and 15 g agar to a volume of 1 l in deionized water. Sterilize by autoclaving. When medium has chilled (to approximately 50 °C), add 1 ml of sterile filtrated ampicillin solution (100 mg/ml in deionized H₂O) and prepare plates.

2.4 Peripheral Blood Mononuclear Cell (PBMC) Isolation by Density Gradient Centrifugation

1. PBMC prep buffer: Dulbecco's phosphate-buffered saline (DPBS), 2% (v/v) fetal bovine serum (FBS).
2. Biocoll separation solution.

2.5 Total RNA Isolation from PBMCs

1. Qiashredder (Qiagen).
2. RNeasy Mini Kit (Qiagen).
3. Ethanol 70%.
4. RNase-free water.

2.6 cDNA Synthesis

1. Superscript III First-Strand Kit (Invitrogen).
2. RNase-free water.

2.7 Gene-Specific Amplification of VHH Regions

1. Q5 High-Fidelity 2× Master Mix (New England Biolabs).
2. Nuclease-free water.
3. Primer sequences for VHH gap repair cloning are given in Table 1.
4. Wizard SV gel and PCR Clean-Up System (Promega).

Table 1
Oligonucleotide primers used in this study (overhang sequences are shown in *italic*)

Name	Sequence (5'–3')
VHH_fwd	<i>CGCTGTTTTTCAATATTTTCTGTTATTGCTAGCGTTTTAGCAGGTGATGTGCAGC</i> TGCAGGAGTCTGGRGGAGG

VHH2_rev	<i>CAATTTTTGTTCAGAACCACCACCACCAGAACCACCACCACCTGGTTGTGG</i> TTTTGGTGTCTTGGG

2.8 Destination Vector (pDest) Digestion

1. *Bsa*I High-Fidelity (20,000 units/ml, New England Biolabs).
2. Cut Smart Buffer 10× (New England Biolabs).
3. Nuclease-free water.
4. Wizard SV gel and PCR Clean-Up System.
5. pDest according to Subheading 2.2.

2.9 Library Transformation into *S. cerevisiae* Strain EBY100

1. *Bsa*I digested pDest according to Subheading 3.5.
2. VHH PCR inserts according to Subheading 3.4.
3. Electroporation buffer: 1 M Sorbitol, 1 mM CaCl₂ × 2H₂O (autoclaved).
4. LiAc buffer: 100 mM LiAc, 10 mM DTT (sterile filtered).
5. 1 M Sorbitol (autoclaved).

2.10 Yeast Surface Display and Selections Using Fluorescence-Activated Cell Sorting (FACS)

1. Dulbecco's phosphate-buffered saline (DPBS).
2. Penta-His Alexa Fluor 647 Conjugate antibody (Qiagen).
3. Anti-HA tag antibody (FITC) (abcam).
4. Target protein, his-tagged.

2.11 Equipment

1. Cryogenic vials.
2. Freezing container.
3. 0.22 μm Steriflip and Steritop filtration units.
4. Shaking flasks (150 ml–3 l volume).
5. Electroporator Gene Pulser Xcell™ (Bio-Rad).
6. 0.2 cm Electroporation Cuvettes (Bio-Rad).
7. MasterPure Yeast DNA Purification Kit (Lucigen).
8. Shaking incubator (20 °C, 30 °C, and 37 °C).
9. Flow cytometry device (i.e., cell sorter).
10. Thermocycler.
11. Device and reagents for agarose gel electrophoresis.
12. Benchtop centrifuge.
13. 9 cm Petri dishes.
14. Cell density meter.
15. BioSpec Nano or equivalent instrumentation.
16. SepMate tubes.

3 Methods

In this section, we describe the construction of large yeast surface display antibody VHH libraries following Lama or Alpaca immunization. In this particular example, two Alpacas (*Vicugna pacos*) and

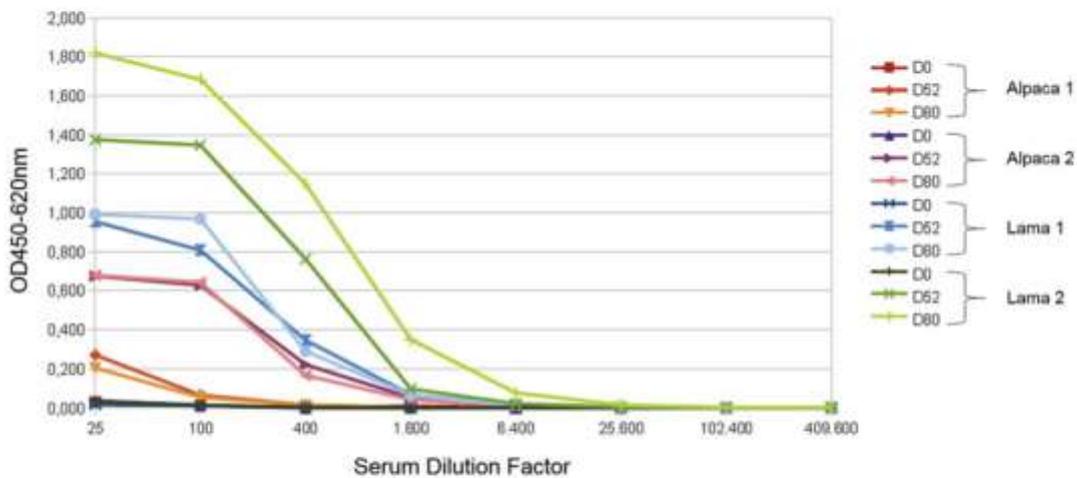

Fig. 4 Example of immune response of two Alpacas and two Lamas after immunization with a protein antigen. Immunizations were performed at Preclinics GmbH and antibody titers were determined by serum ELISA

two Lamas (*Lama glama*) were immunized at Preclinics GmbH (<http://www.preclinics.com/>) with a protein antigen. During the immunization procedure, Preclinics GmbH assessed the antigen-specific immune response in a serum ELISA, as exemplarily shown in Fig. 4. Afterwards, total RNA was isolated from 100 ml PBMCs followed by cDNA synthesis which was subsequently used for gene-specific amplification. In order to allow for a broader applicability of this herein described protocol, we also include methods for the generation of cDNA starting from whole blood. Gene-specific oligonucleotide sequences for the amplification of camelid VHH repertoires can also be found elsewhere [16, 24]. However, all protocols, components, concentrations and volumes given below can be used without any modification for the introduction of VHH diversities into yeast surface display libraries. Additionally, in Sub-heading 3.10, we also present a labeling strategy for the detection of surface display and antigen binding using fluorescence-activated cell sorting.

3.1 PBMC Isolation by Density Gradient Centrifugation

1. Dilute blood samples with an equal volume of PBMC prep buffer.
2. Fill SepMate tubes with 16 ml Biocoll Separation Solution.
3. Transfer approx. 30 ml diluted blood carefully into the SepMate tubes. Avoid subsidence of the blood under the separating disc.
4. Centrifuge for 20 min at $1200 \times g$ and room temperature with medium acceleration and deceleration profile.

5. Remove blood plasma phase by pipetting. Please note that the PBMC fraction is located directly below and should not be affected by pipetting.
6. If PMC cells are aggregated at SepMate inner surface, remove them mechanically by scraping.
7. Decant residual blood plasma and PBMC into clean tube (ensure that no erythrocytes are transferred) and add 50 ml PBMC prep buffer.
8. Centrifuge for 8 min at $300 \times g$ and room temperature with maximum acceleration and medium deceleration profile. Discard supernatant.
9. Wash cells twice by resuspending in 50 ml volume with PBMC prep buffer and repeat centrifugation as in **step 8**, respectively.
10. Resuspend cells in defined volume of PBMC prep buffer and count PBMC number.

3.2 Total RNA Isolation from PBMCs

1. Pellet 1×10^7 cells by centrifugation for 2 min at room temperature and $1200 \times g$ (microfuge).
2. Lyse cells by resuspending in 600 μ l of RLT and subsequent vortexing or pipetting.
3. Add the lysate into Qiashredder column in a 2 ml collection tube and centrifuge for 2 min at maximum speed and room temperature.
4. Remove the Qiashredder column and determine the volume of homogenized lysate before adding same amount of 70% ethanol.
5. Transfer the sample into RNeasy spin column in a 2 ml collection tube and centrifuge for 60 s at $8000 \times g$ and room temperature. Discard flow-through. If sample volume exceeds 700 μ l, centrifuge aliquots stepwise.
6. Add 700 μ l of RW1 buffer into RNeasy spin column. Centrifuge for 60 s at $8000 \times g$ and room temperature. Discard flow-through.
7. Wash the sample twice by adding 500 μ l of RPE buffer and successive centrifugation for 60 s at maximum speed and room temperature, respectively.
8. Transfer RNeasy spin column containing bound RNA into a clean collection tube and add 50 μ l of RNase-free water.
9. Incubate for 15 min at room temperature.
10. Eluate RNA by centrifugation for 60 s at maximum speed and room temperature. To increase RNA yield load flow-through again onto RNeasy, spin column and repeat the latter centrifugation step.

3.3 cDNA Synthesis

1. Prepare a RNA and primer mix by adding 5 μ l RNA solution from RNA isolation as template, 1 μ l random hexamer primers (50 ng/ μ l) as well as 1 μ l of 10 mM dNTP mix. Add 10 μ l with RNase-free water.
2. Place the mix in thermocycler at 65 °C for 5 min, followed by 60 s incubation on ice.
3. Prepare reverse transcriptase Master Mix by combining 2 μ l RT buffer, 4 μ l 25 mM MgCl₂, 2 μ l 100 μ M DTT as well as 1 μ l RNaseOut (40 U/ μ l), and 1 μ l SuperScript III RT (200 U/ μ l).
4. Add an equal volume of reverse transcriptase Master Mix to the RNA and primer mix.
5. Incubate the reaction solution in a thermocycler with 12 min at 25 °C followed by 52 min at 50 °C and as final step 5 min at 85 °C.
6. Add 20 μ l of RNase H solution and incubate at 37 °C for 20 min.

3.4 Amplification of Lama and Alpaca HcAbs Variable Domains (VHHs)

1. Place PCR tube on ice and add 25 μ l Q5 high fidelity 2 \times Master Mix. Add 1 μ l (100 ng/ μ l) of DNA encoding for alpaca VHH region as template as well as 2.5 μ l corresponding forward primer and 2.5 μ l reverse primer (out of a 10 μ M stock, primer sequences are listed in Table. 1) and 19 μ l nuclease-free water. Alpaca VHHs can be amplified using primer combination VHH_fwd and VHH1_rev. Lama VHH regions can be amplified using the VHH_fwd and both reverse oligonucleotides (*see Note 2*).
2. Carry out PCR using the following parameters: Initial denaturation at 98 °C for 30 s. 30 cycles of 10 s denaturation at 98 °C, 30 s primer annealing at 57 °C, and 30 s elongation at 72 °C, followed by final step at 72 °C for 2 min.
3. Analyze PCR products by 1–2% (w/v) agarose gel electrophoresis. Amplified VHH region genes should give a distinct band at approx. 500 bp. Purify PCR products using Wizard[®] SV Gel and PCR Clean-Up System according to the manufacturer's instruction (*see Note 3*). Determine DNA concentration via BioSpec Nano or equivalent instrumentation. PCR products might be stored at –20 °C.

3.5 Destination Vector (pDest) Digestion

1. Place PCR tube on ice and add 40 μ g of pDest (1 mg/ml), 8 μ l Cut Smart 10 \times . Buffer as well as 2 μ l BsaI-HF (20000 U/ml) in a final volume of 80 μ l (add nuclease-free water in order to achieve this volume).
2. Carry out reaction at room temperature overnight.
3. Analyze digestion product by 1–2% (w/v) agarose gel electrophoresis. Successful digestion should give a distinct band at

approx. 6000 bp. Purify digestion reaction using Wizard[®] SV Gel and PCR Clean-Up System according to the manufacturer's instruction.

3.6 Yeast Transformation for Library Establishment

In the following section, we describe library construction steps as modified version of the improved *S. cerevisiae* yeast transformation protocol of Benatuil and colleagues [29]. Therefore, it is herein only presented in brief. In this protocol all centrifugation steps to pellet yeast cells are performed at $4000 \times g$ for 3 min.

1. Incubate EBY100 overnight to stationary phase in YPD media at 120 rpm and 30 °C.
2. Inoculate 500 ml fresh YPD media with the overnight culture to an OD₆₀₀ of about 0.3.
3. Incubate cells at 30 °C and 120 rpm until OD₆₀₀ reaches about 1.6–1.9.
4. Centrifuge cells and remove supernatant.
5. Wash cells twice by resuspension in 250 ml ice-cold water followed by a wash step using 250 ml ice-cold electroporation buffer.
6. Resuspend cells in 100 ml LiAc-buffer and incubate for 30 min at 30 °C and 120 rpm.
7. Centrifuge cells and wash afterwards once with 250 ml ice-cold electroporation buffer.
8. Resuspend cell pellet in electroporation buffer to a final volume of approx. 5 ml. This results in ten electroporation reactions with approx. 400 µl electro-competent EBY100 each.
9. Add 4 µg digested pDest and 12 µg VHH PCR product to 400 µl electro-competent cells per reaction.
10. Transfer cell-DNA mix to ice-cold electroporation cuvette (0.2 cm). Electroporate at 2500 V. Time constant should range from 3.0 to 4.5 ms. Transfer cells from each electroporation reaction into 8–10 ml of a mixture of YPD and 1 M sorbitol (1:1 ratio). Incubate for 1 h at 30 °C and 120 rpm.
11. Centrifuge cells and resuspend cell pellet in 10 ml SD-Trp media to calculate library size by dilution plating (*see Note 4*, SD-Trp agar plates; estimate number of transformants after 72 h).
12. Decant cells in 1 l in SD-Trp media and incubate for 2 days at 30 °C and 120 rpm.
13. Transfer library to SD Low -Trp medium. To this end, transfer at least a tenfold excess of cells as calculated by dilution plating. Inoculate at an OD₆₀₀ of ~1.0. An absorbance value of 1 at 600 nm corresponds to approximately 1×10^7 cells per ml.

14. Incubate for two more days at 30 °C and 120 rpm.
15. The final library is henceforth prepared for long-term storage (*see* Subheading 3.8) or screening via FACS. To evaluate the quality of the final library, the authors recommend sending out at least 100 clones for sequencing (*see* Note 5).

3.7 Sequencing of Display Vector from Yeast Cells

1. Pick clones (e.g., from serial dilution) and inoculate approximately 10 ml SD-Trp medium in a baffled flask followed by incubation for 48 h at 30 °C and 120 rpm. Subsequently, isolate display plasmid using the MasterPure Yeast DNA Purification Kit following the manufacturer's protocol.
2. Transform 50 µl electro-competent *E. coli* Top10 cells with 5 µl isolated plasmid.
3. After incubation for approximately 60 min in LB medium without antibiotics, plate cells on LB Amp agar plates and incubate overnight at 37 °C. Afterwards pick single colonies and inoculate 700 µl LB Amp media in a Masterblock microplate. Incubate overnight at 37 °C and 700 rpm.
4. Mix 60 µl of *E. coli* Top10 culture with 40 µl glycerol solution (50% v/v) in an appropriate microplate. Deep-freeze at –80 °C until sending out for sequencing.

3.8 Yeast Library Cryopreservation for Long-Term Storage

1. Harvest cells from a freshly grown SD-Trp culture by centrifugation.
2. Inoculate SD Low -Trp medium with cells to an OD₆₀₀ of 1 and cultivate for 48–72 h at 30 °C and 120 rpm. Library diversity should be oversampled by at least the factor of ten.
3. Harvest cells by centrifugation and remove supernatant.
4. Wash cells once with DPBS. Afterwards pellet cells by centrifugation, decant, and discard supernatant.
5. Resuspend cells in yeast library freezing solution with final cell concentrations of approximately 1×10^{10} cells/ml and transfer suspensions into cryogenic vials.
6. Freeze vials at –80 °C.

3.9 Induction of VHH Expression for Antibody Surface Display

1. Thaw an aliquot of the frozen library at room temperature and resuspend cells in SD-Trp.
2. The total number of cells in the starting culture should exceed the calculated library diversity at least ten times.
3. Incubate overnight at 30 °C and 120 rpm.
4. Harvest at least the number of cells corresponding to a tenfold excess of the library diversity by centrifugation and resuspend cells in SG -Trp medium to an initiate OD₆₀₀ of 1. Cultivate cells for at least 24 h at 20 °C and 120 rpm for expression of VHHs.

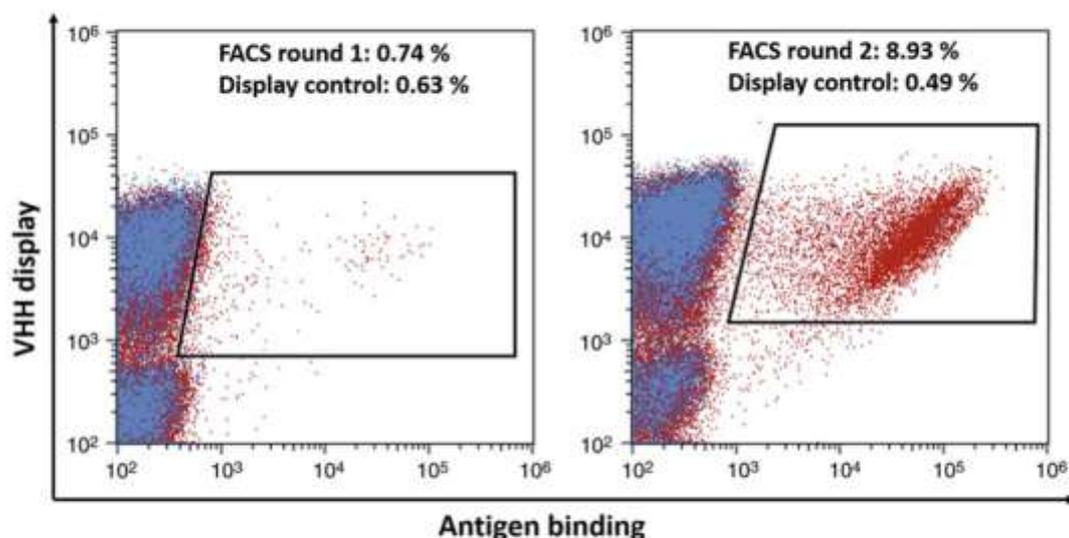

Fig. 5 Detection of VHH display and antigen binding of yeast surface display library candidates using FACS. Overlays of VHH display control (blue) and antigen binding yeast cells (red). Blue: yeast cells labeled with Penta-His Alexa Fluor 647 Conjugate antibody and anti-HA tag antibody (FITC) only. Red: staining for VHH surface display (same detection antibodies as for display control) as well as for antigen binding. Left: FACS sorting round 1. Right: FACS sorting round 2. Sorting gates are shown as well as percentage of cells in sorting gate

3.10 Detection of Yeast Surface Display and Antigen Binding by Fluorescence-Activated Cell Sorting (FACS)

In the following chapter, we describe a labeling strategy to detect surface expression of VHH molecules via binding of a fluorescently labeled anti-HA tag antibody (FITC) as well as antigen binding via his-tag staining (Penta-His Alexa Fluor 647 Conjugate antibody). An equivalent staining procedure can be carried out for library sorting (*see* Notes 6 and 7). Please note that the fluorophores should be shielded from light and labeling steps are performed on ice. For all FACS sorting rounds as well as for flow cytometric analysis, we recommend staining an antibody display control (without antigen) in order to be able to adjust sorting gates accordingly (Fig. 5). Furthermore, a positive control, i.e., a single clone displaying a target-positive VHH should be used to ensure functional integrity of labeling reagents as well as target proteins. It is also possible to carry out positive control staining with different antibody formats. Consequently, staining reagents need to be adapted accordingly (e.g., detection of Fab fragment presentation via staining of the constant domain of the light chain).

3.10.1 Antibody Display Control

1. Pellet approximately 2×10^7 cells by centrifugation and remove supernatant. Wash cells two times with DPBS and resuspend cells in 40 μ l DPBS. Incubate on ice for about 30 min.

2. Wash cells twice with DPBS and resuspend in 40 μ l DPBS containing Penta-His Alexa Fluor 647 Conjugate antibody (diluted 1:20) and anti-HA tag antibody (FITC) (diluted 1:20), followed by incubation on ice for 30 min.
3. Wash cells again two times and resuspend the cell pellet finally in 600 μ l DPBS. Keep on ice protected from light until FACS analysis.

3.10.2 Library Staining

The following section describes staining protocol of antibody displaying yeast cells regarding VHH surface expression as well as target binding. Essentially the same protocol can be used to label positive controls and libraries in general. Scale up for sorting purposes (*see Note 6*).

1. Pellet 2×10^7 yeast cells by centrifugation and remove supernatant. Wash cells twice with DPBS and resuspend in 40 μ l DPBS containing antigen with a concentration of 1 μ M (*see Note 8*). Incubate cells on ice for 30 min.
2. Wash cells two times and resuspend in 40 μ l DPBS containing Penta-His Alexa Fluor 647 Conjugate antibody (diluted 1:20) and anti-HA tag antibody (FITC) (diluted 1:20), followed by incubation on ice for 30 min (*see Note 9*).
3. Wash cells again two times and resuspend the cell pellet finally in 600 μ l DPBS. Keep on ice protected from light until FACS analysis.

3.10.3 Further Proceeding with Cells After FACS Sorting

This section describes briefly the treatment of the sorted cells after FACS analysis for further cytometric analysis rounds and cell storage.

1. Transfer sorted cells collected in sorter tube containing 500 μ l DPBS into corresponding volume of SD media (approximately 20 ml media per 1×10^6 cells). Incubate at 30 °C and 120 rpm for 2 days.
2. Count cell number and induce VHH expression (*see Note 6*) by media exchange, as described in Subheading 3.9.
3. Deep-freeze remaining cells according to Subheading 3.8 for long-term storage.

4 Notes

1. In general, overhang sequences were part of constant components of the display system. The *N-terminal* overhang comprised nucleotides that were identical with those of a part of the Aga2p signal peptide, whereas *C-terminal* overhang was homologous to the glycine-serine linker fused to the myc-tag.

The herein described pDest allowed for N-terminal presentation of VHH moieties (i.e., free N-terminus of VHH and C-terminus fused to Aga2p). C-terminal display of VHHs is also a valid strategy for surface expression as already described by our group for the display of shark-derived single-domain antibodies [29–31].

2. Reverse primers were designed to anneal in the hinge region of camelid-derived IgG2b and IgG3b isotypes. Another alternative is the utilization of oligonucleotides annealing in framework region 4 of the VHH domain.
3. By using the primer sets shown in Table 1, one co-amplifies also the VH as well as CH1 region of conventional IgG antibodies. This results in an unwanted product with a size of approximately 800–900 bp on the agarose gel. We typically do not gel-excise the VHH-specific band since this would require a second-step re-amplification and a potential bias. Still, this crude mixture delivers nearly exclusively VHH domains after library establishment.
4. One transformation electroporation reaction usually yields in approximately 1×10^7 to 5×10^7 unique EBY100 clones. Scale up gap repair cloning and electroporation reactions by parallelization to obtain a sufficient library size. This is especially required for the construction of libraries from non-immunized animals.
5. For quality maintenance we recommend sequencing of the constructed library. Thus, the sequencing primer should be designed with respect to VHH region coverage in a single run. To this end, oligonucleotides should anneal approximately 60 bp upstream of the variable region.
6. In general, labeling steps are performed with 2×10^7 cells in a volume of 40 μ l. For library sorting purposes, scale up in order to be able to sample a sufficient number of clones. By increasing the numbers of cells, volumes and amounts of labeling reagents should be increased proportionally. We recommend oversampling the generated diversity by at least the factor of ten. However, when large libraries are being generated, the limiting factor is throughput by FACS. For the first round of FACS, a maximum number of cells should be sorted. For subsequent sorting rounds, we typically oversample the number of isolated cells from the previous round by the factor of ten.
7. A variety of labeling reagents are commercially available. Thus, different combinations of fluorescent dyes and detection reagents are possible. For fluorophore selection, please note that no overlapping of excitation and emission spectra occur. Otherwise, appropriate compensation needs to be applied on the FACS device. Guidance should be given by the respective manufacturer.

8. To enhance stringency, the antigen concentration can be reduced significantly. However, we recommend starting sorting at an antigen concentration of 1 μ M for initial rounds and to successively reduce the concentration as soon as cells are enriched for an antigen-binding population.
9. When working with non-immunized antibody repertoires, different secondary detection reagents should be alternated to avoid enrichment of off-target binders.

Acknowledgments

We like to thank Preclinics GmbH for collaborating on this project.

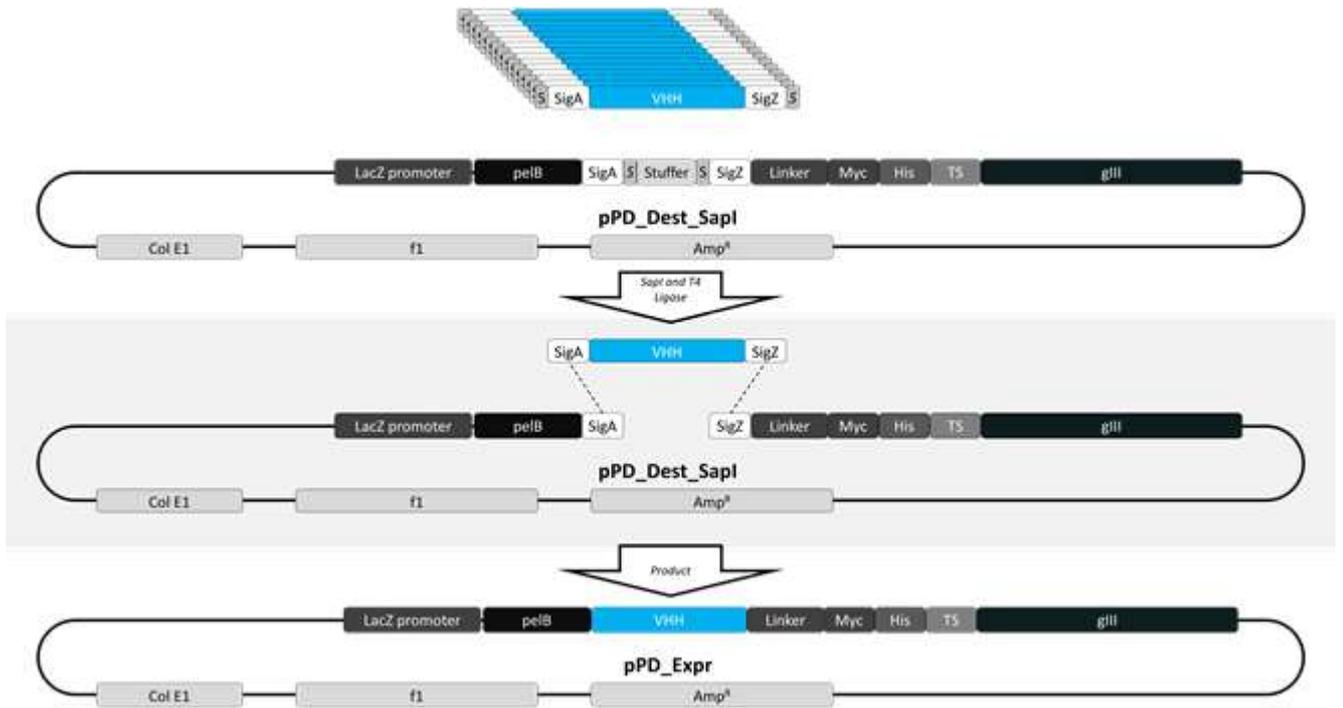

Figure S1: Schematic overview of the one-step generation process of phage display plasmids for the construction of VHH-derived single domain antibody libraries. The destination plasmid (pPD_Dest_SapI) as well as the PCR-amplified VHH repertoire contains or is flanked by SapI recognition sites in opposite orientations (S: GCTCTTCN, S': NGAAGAGC). Complimentary overhangs i.e. signature sequences (SigX) after SapI digestion enable the defined one-pot assembly during ligation resulting in the final display plasmid (pPD_Expr). ColE1: origin of replication. f1: origin of replication. Amp^R: Ampicillin resistance gene, pelB: leader sequence. Linker: amino acids AAAGS, Myc: c-Myc epitope EQKLISEEDL, His: hexahistidine tag, TS: trypsin site KDIR, gIII. gene encoding for phage protein pIII. Note that an amber stop codon is introduced between the hexahistidine tag and the trypsin site.

Figure S2: Western Blot analysis of different camelid-derived single domain VHH libraries as displayed on the surface of phage particles. M: marker; H1, H2, H3: Helper phage (10^9 , 10^8 , 10^7 phage particles loaded on the gel; L1.1: Llama 1 VHH sub-library short hinge; L1.2: Llama 1 VHH sub-library long hinge; L2.1: Llama 2 VHH sub-library short hinge; L2.2: Llama 2 VHH sub-library long hinge; C: Chicken-derived ScFv library. For each library, 10^9 phage particles (pfu) were loaded on the gel. Bands corresponding to pIII, VHH:pIII fusion and ScFv:pIII fusion are indicated by arrows. Western Blot was developed with mouse anti-pIII antibody (MobiTec) and peroxidase conjugated goat anti-mouse antibody (Jackson Immuno Research).

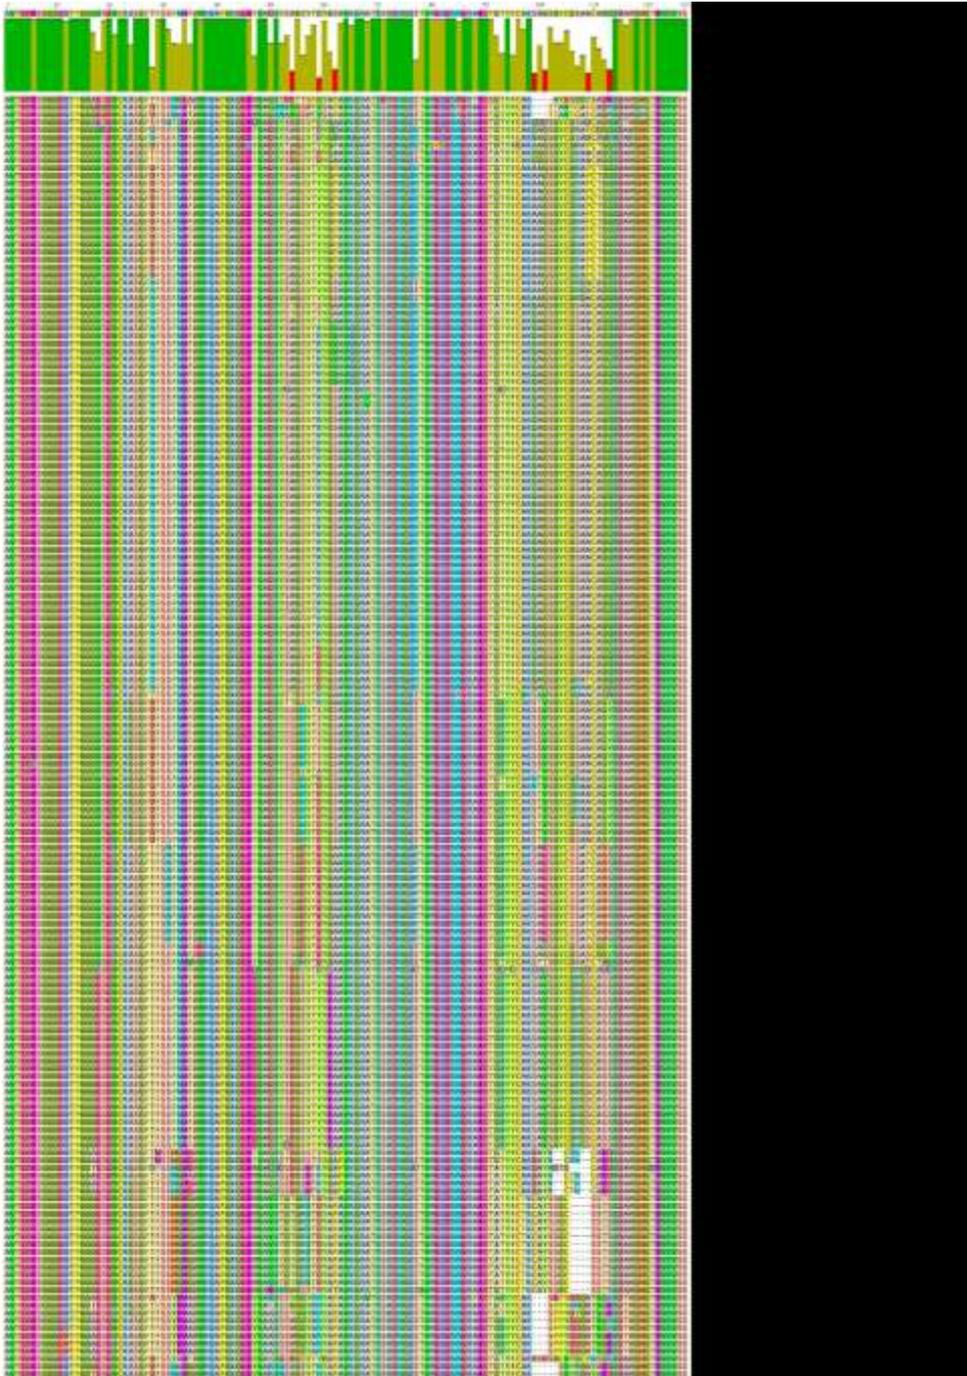

Figure S3: Multiple sequence alignment of VH after panning the EGFR-immunized chicken scFv library via Phage Display. Clusters are indicated. For calculation of unique clones, sequences containing ambiguities (X) were not taken into account. Sequences containing stop-codons or frame-shifts were excluded from analysis. Alignment was created using MUSCLE Alignment tool within Geneious Prime software (www.geneious.com).

Figure S4: Multiple sequence alignment of VL after panning the EGFR-immunized chicken scFv library via Phage Display. For calculation of unique clones, sequences containing ambiguities (X) were not taken into account. Sequences containing stop-codons or frame-shifts were excluded from analysis. Alignment was created using MUSCLE Alignment tool within Geneious Prime software (www.geneious.com).

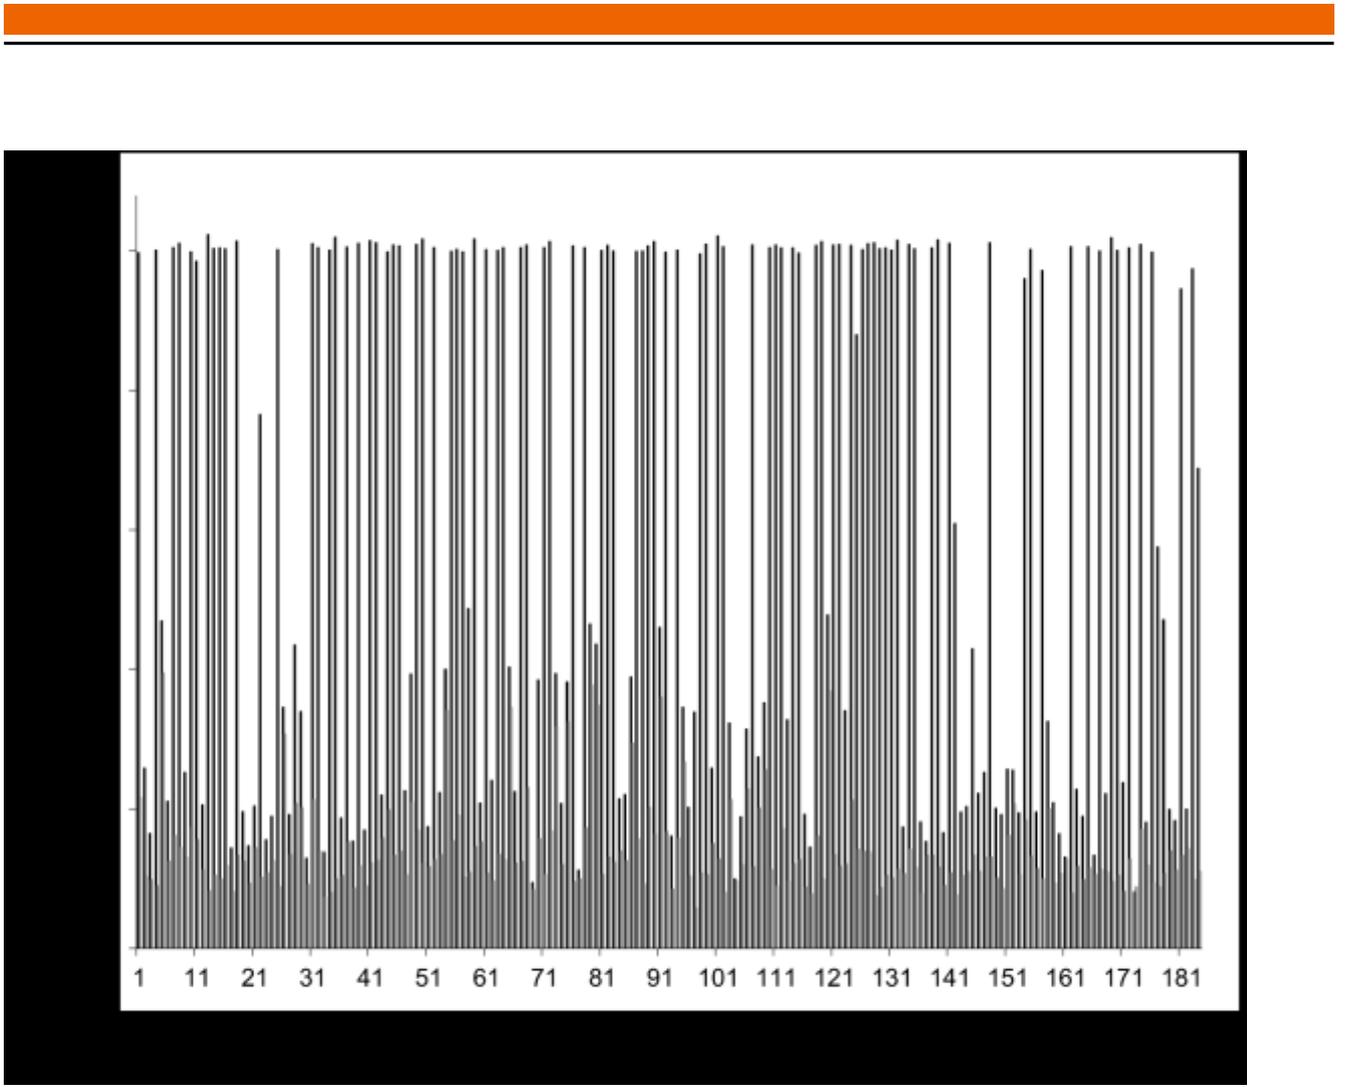

Figure S5: ELISA screening after microtiter production of selected chicken scFv library candidates in *E. coli*. Black: ELISA signal against EGFR, grey: Absorbance at 450 nm against unrelated negative control antigen.

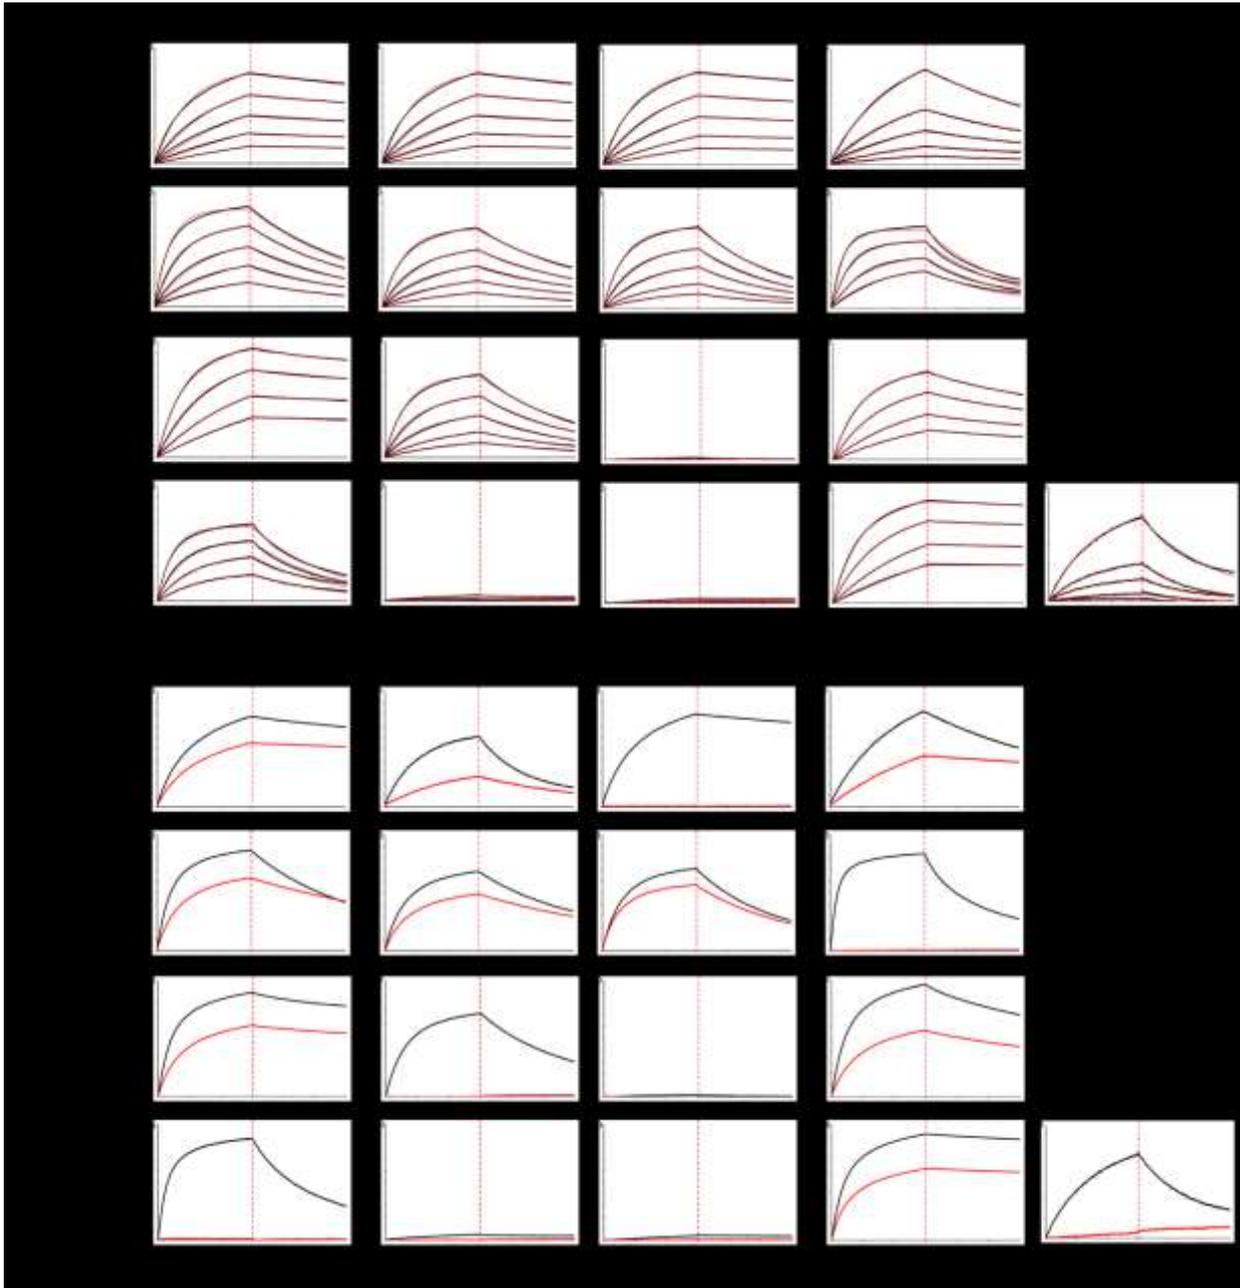

Figure S6: (A) Binding kinetics of phage display-derived anti-EGFR scFvs (78_H06-70_B02) and VHHs (75_A11-75_H11) as determined via BLI. Antibody binders were loaded onto AHC tips. Association was measured against soluble human EGFR (ECD, concentration range: 100 nM – 6.25 nM). (B) Species-crossreactive binding against recombinant human EGFR (ECD, black) and recombinant mouse EGFR (ECD, red) for given antibody derivatives. Antibodies were captured onto AHC tips. Binding was measured at a concentration of 100 nM antigen.

Figure S7: Multiple sequence alignment of VHH after panning the EGFR-immunized Llama-derived VHH libraries via Phage Display. For calculation of unique clones, sequences containing ambiguities (X) where not taken into account. Sequences containing stop-codons or frame-shifts were excluded from analysis. Alignment was created using MUSCLE Alignment tool within Geneious Prime software (www.geneious.com).

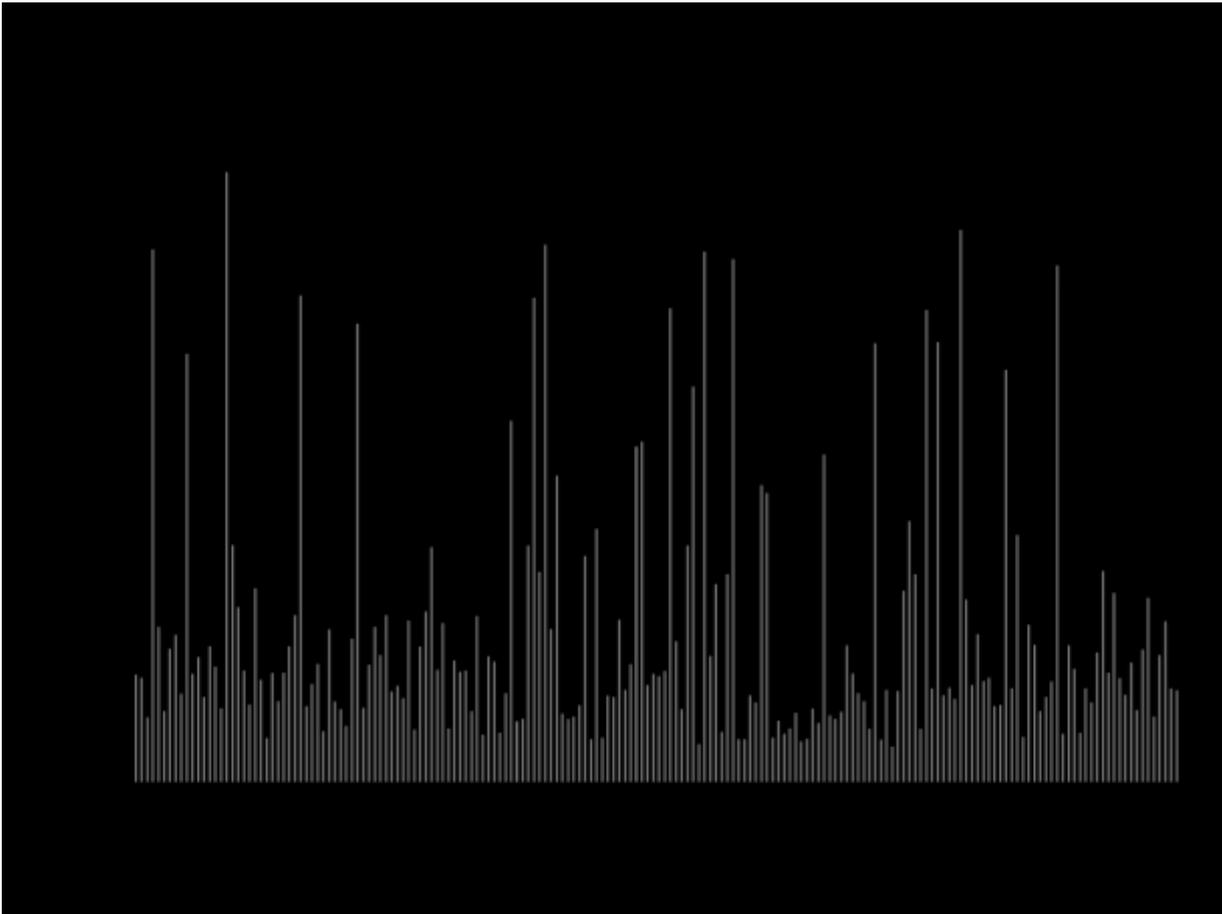

Figure S8: ELISA screening after microtiter production of selected camelid VHH library candidates in *E. coli*. A representative block of 188 consecutive clones as assessed by ELISA is shown. Black: ELISA signal against EGFR, grey: Absorbance at 450 nm against unrelated negative control antigen.

Table S1: Oligonucleotide primers used in this study. TypeIIIs restriction sites are shown in italic, resulting overhangs i.e. signature sequences are underlined.

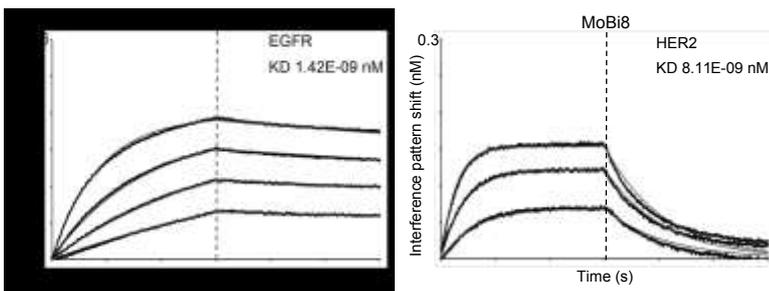

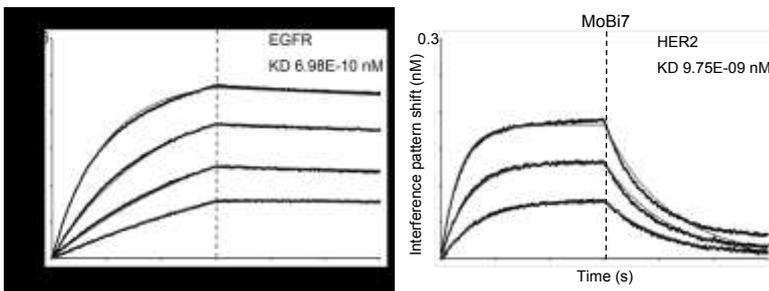

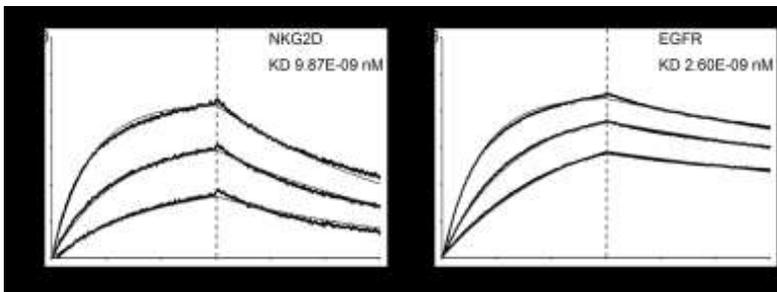

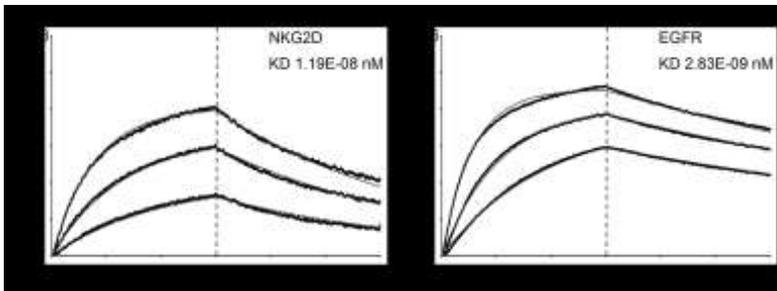

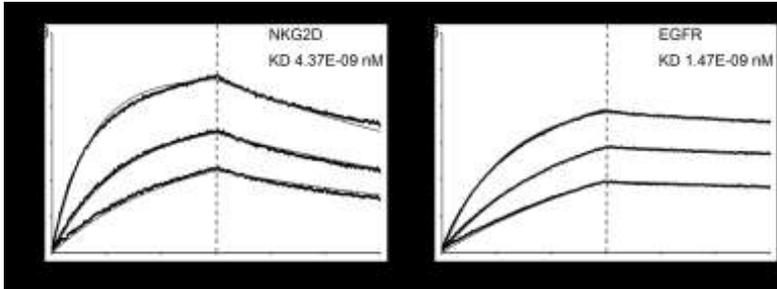

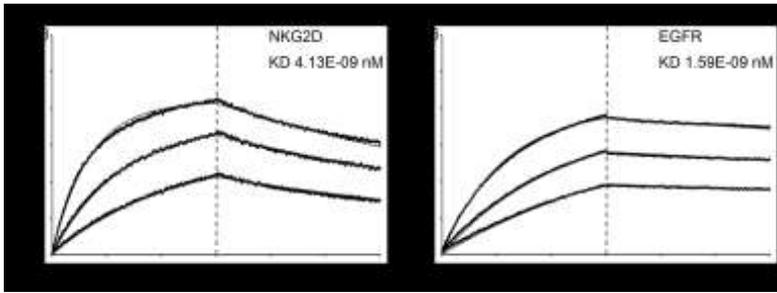

Fig. S1: (A) Amino acid sequences of VHHs used in this study. HER2-specific VHH_2Rb17c sequence was obtained from WO2016016021, EGFR_722C03 was generated by combining camelid immunization and yeast surface display, EGFR_9G8 was derived from PDB:KRP and NKG2D_ET1F08 from WO2017081190. (B) Design examples of VHHs as grafted on constant regions of human antibodies (IgG1).

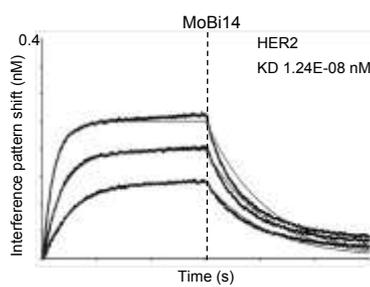

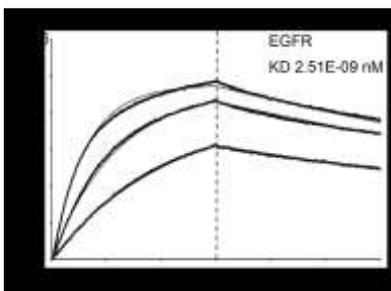

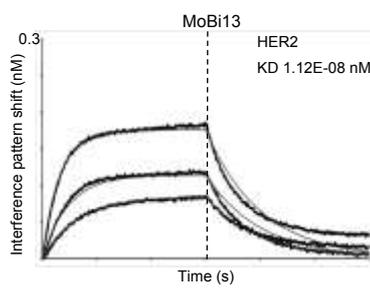

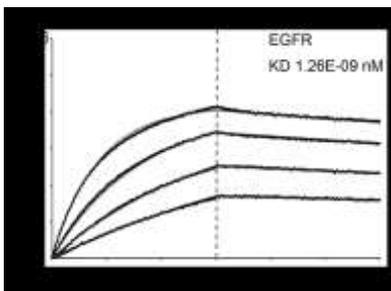

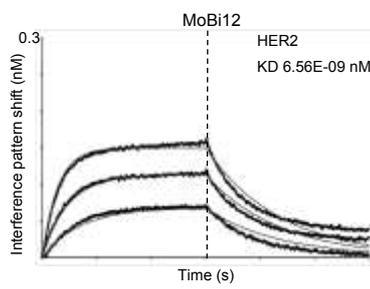

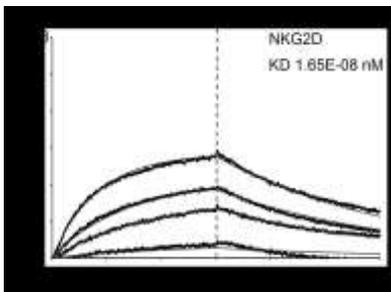

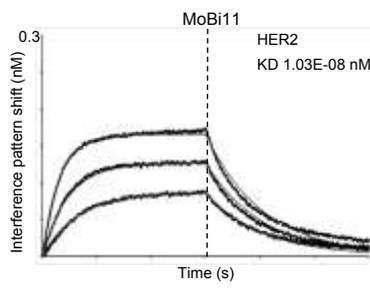

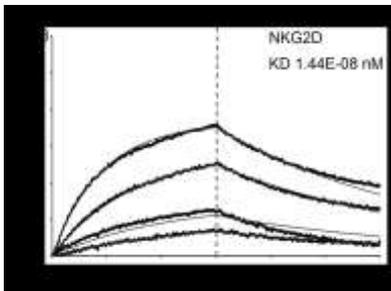

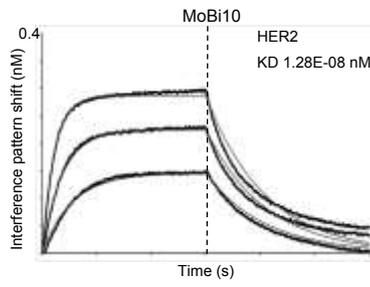

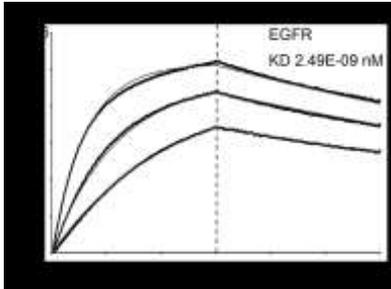

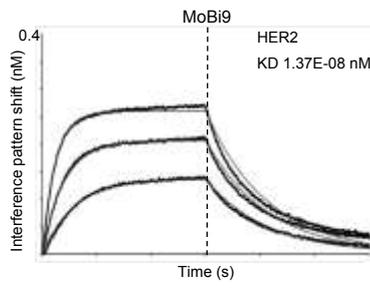

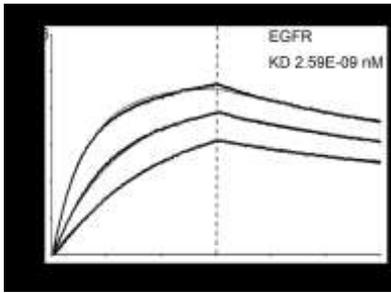

Table S1: Binding affinities (KD) and corresponding on-rates (Kon) and off-rates (Koff) for each paratope of the antibody molecules tested in this study. Every KD value was determined individually via biolayer interferometry analysis.

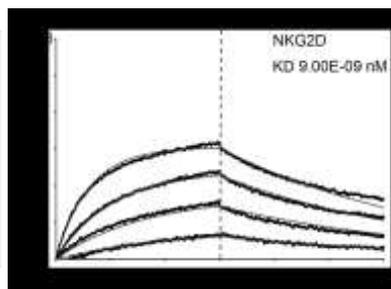

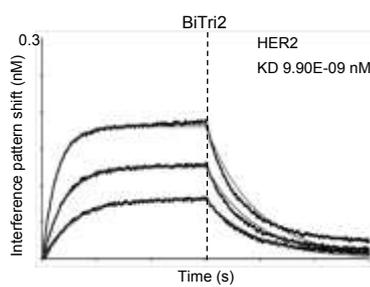

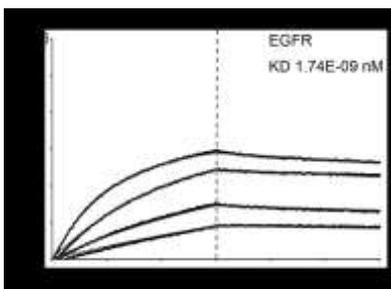

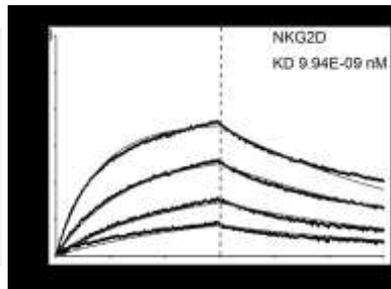

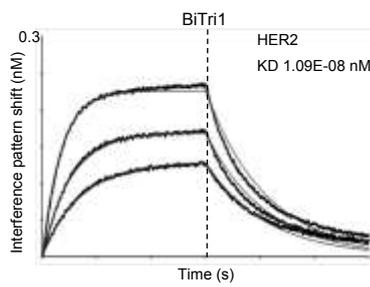

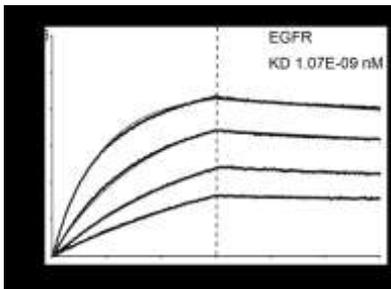

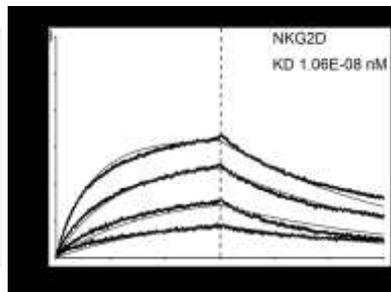

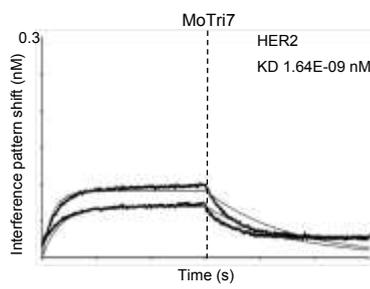

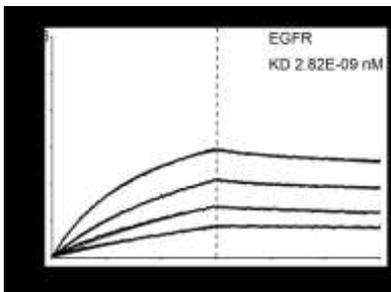

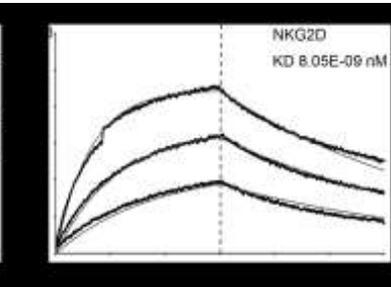

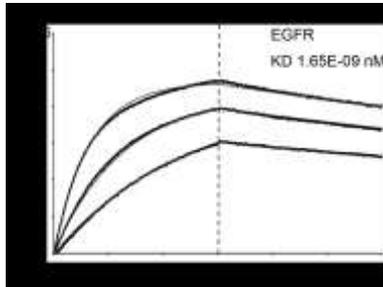

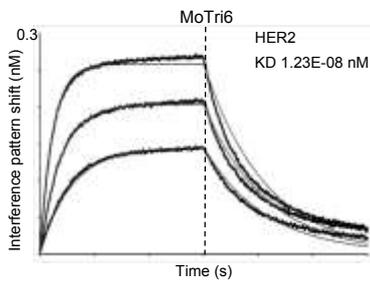

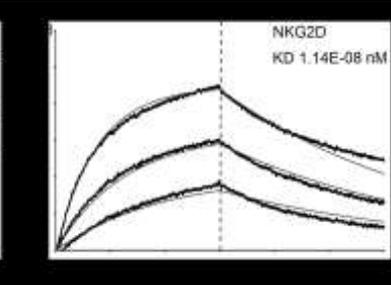

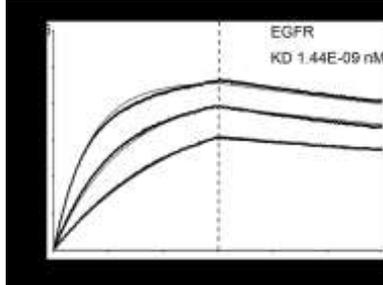

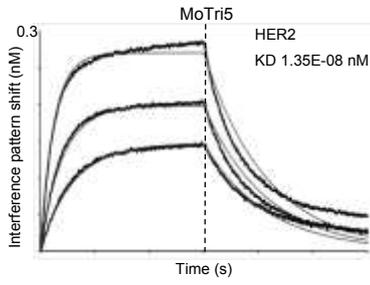

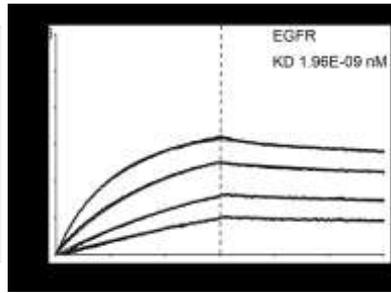

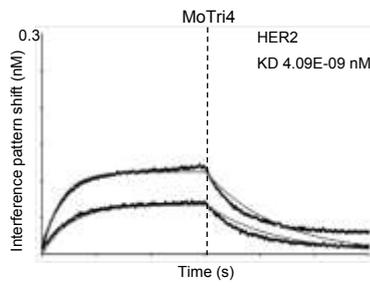

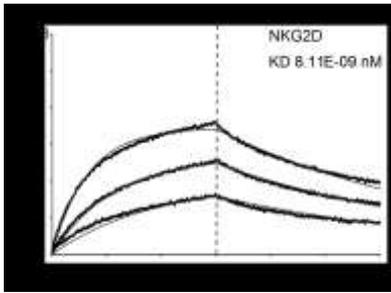

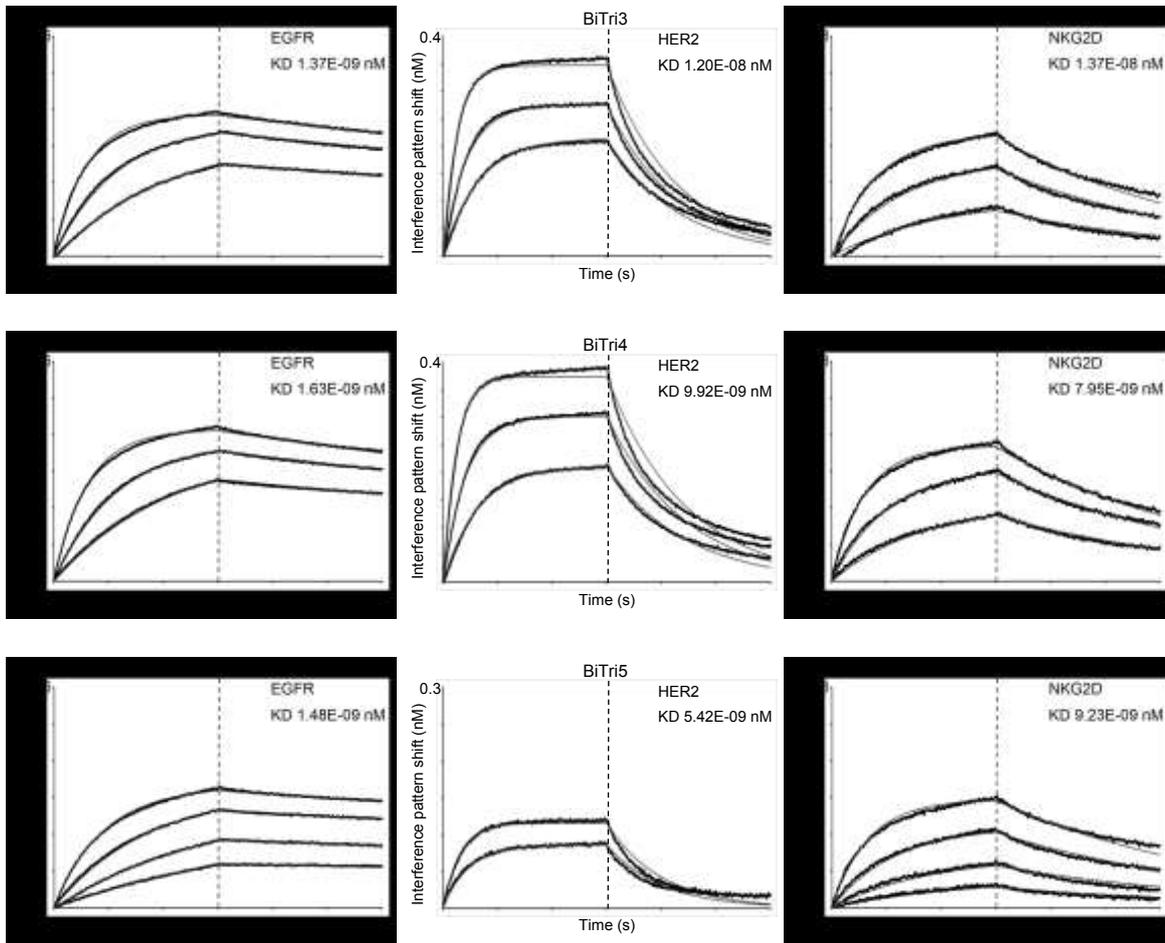

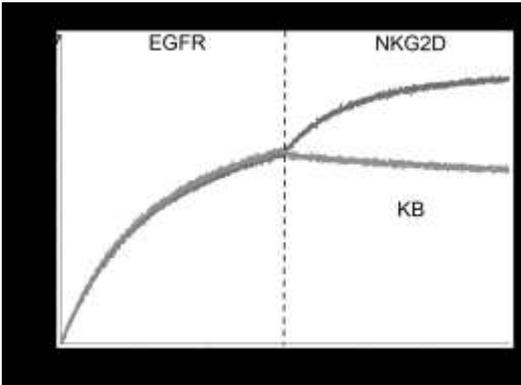

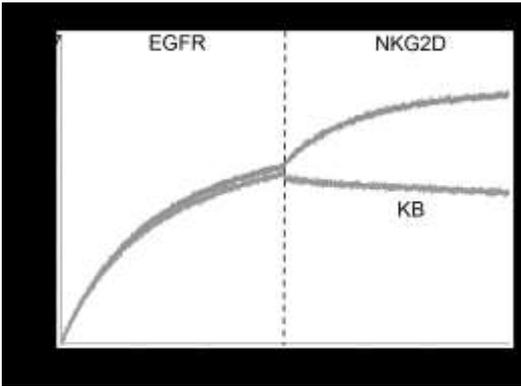

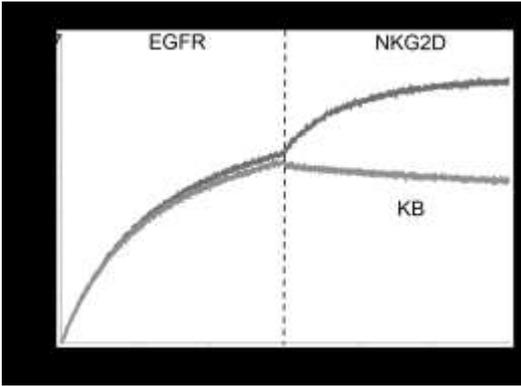

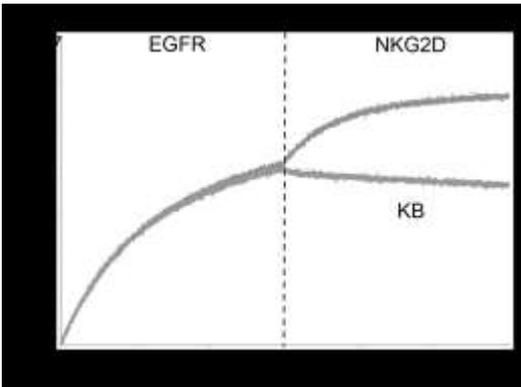

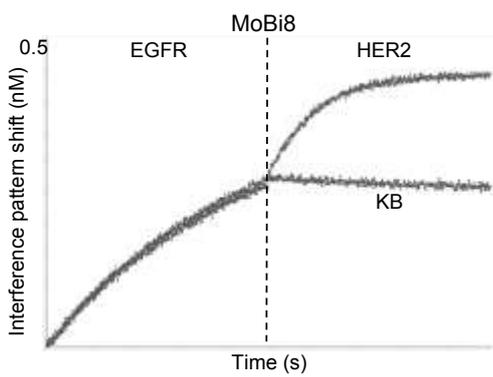

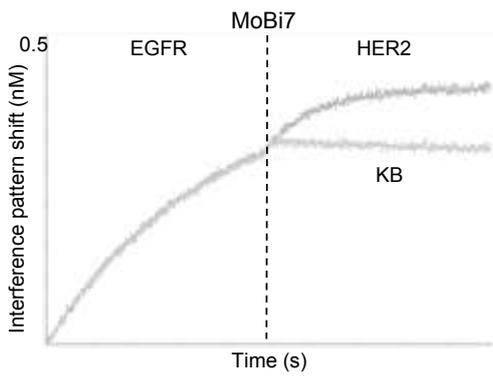

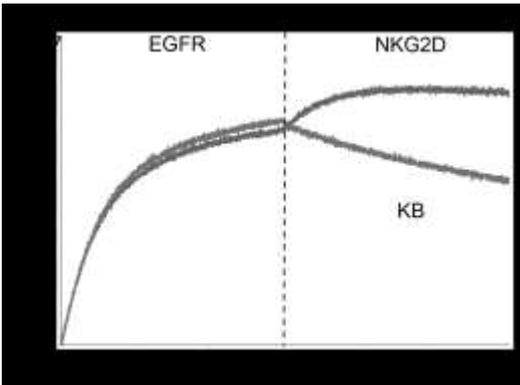

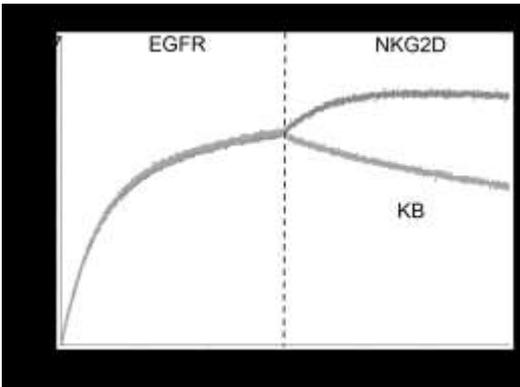

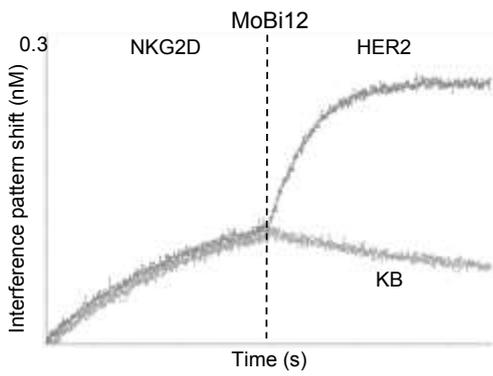

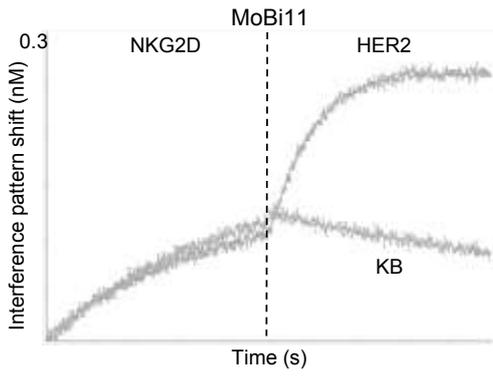

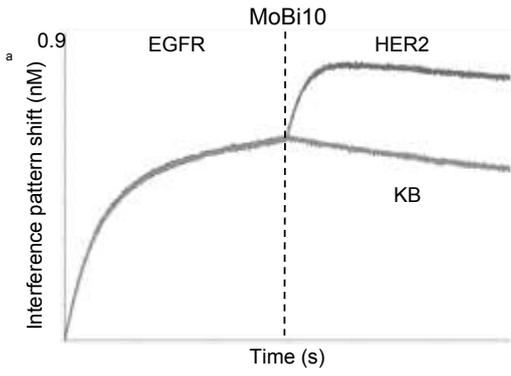

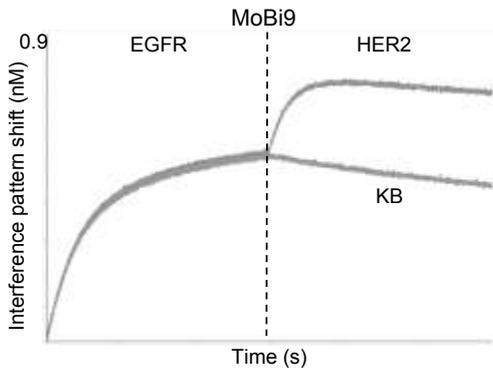

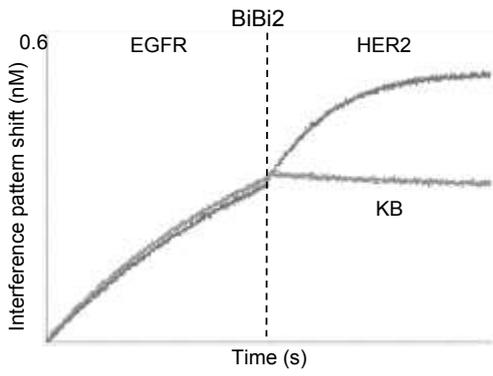

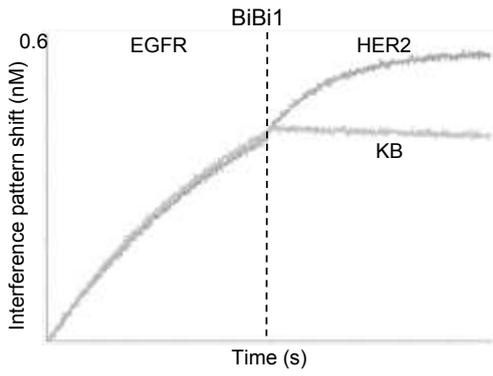

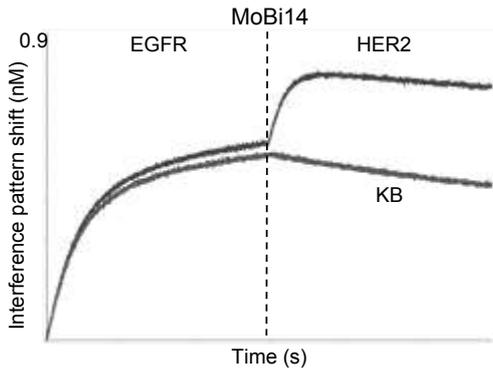

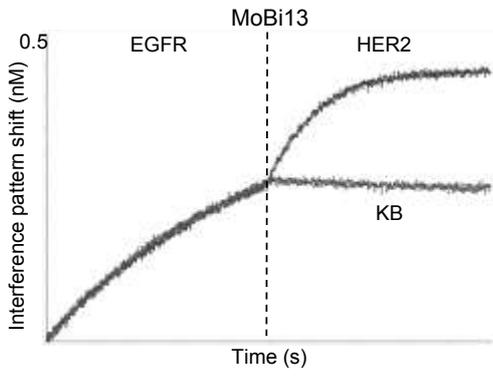

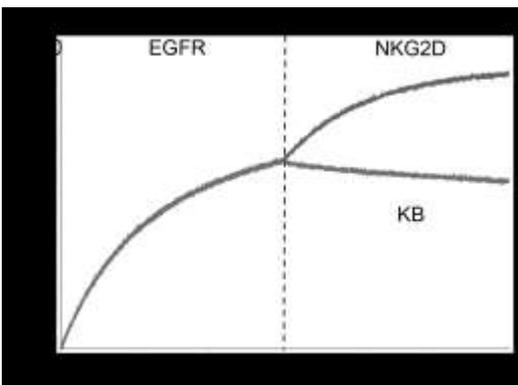

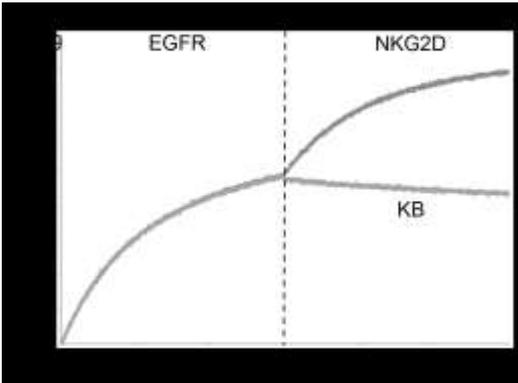

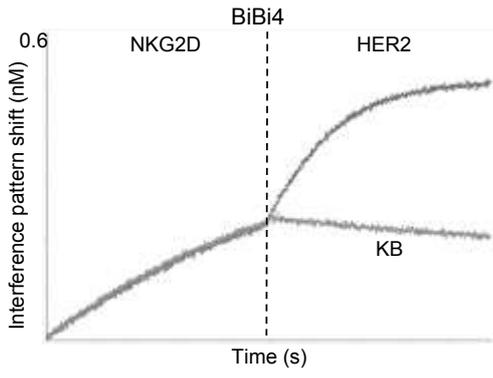

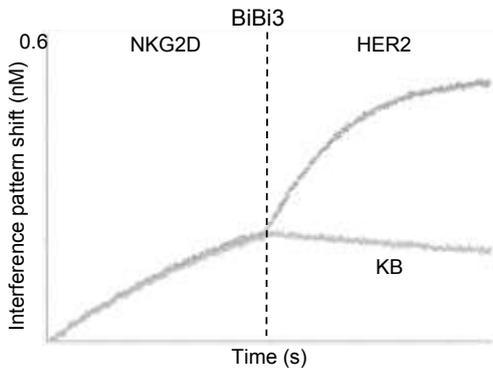

Fig. S2: Biolayer interferometry analysis for affinity determination of antibody molecules used in this study. One armed monovalent monospecific, one armed monovalent bispecific, bivalent bispecific, monovalent trispecific and bivalent trispecific molecules were characterized. Antigen binding was conducted for each antibody paratope separately with the respective antigen (EGFR, NKG2D and Her2) for 300 s, followed by a dissociation step in kinetics buffer for another 300 s.

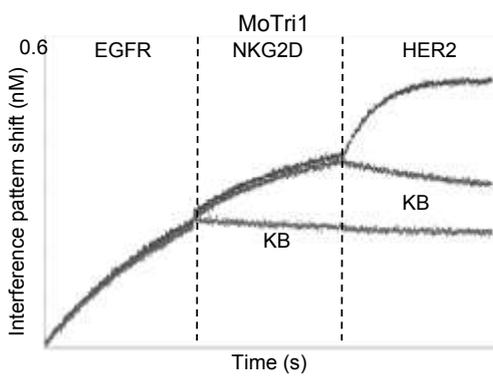

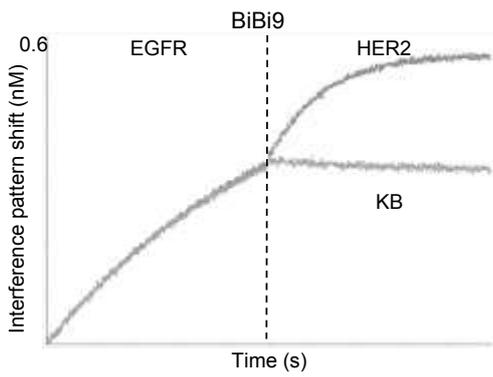

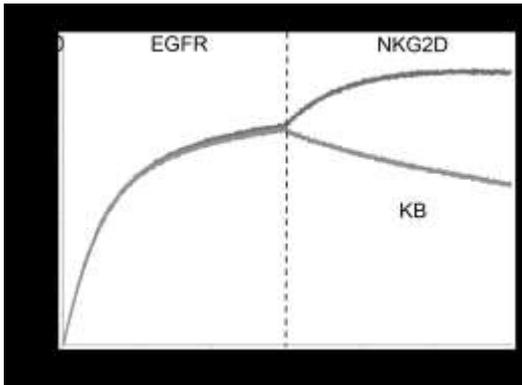

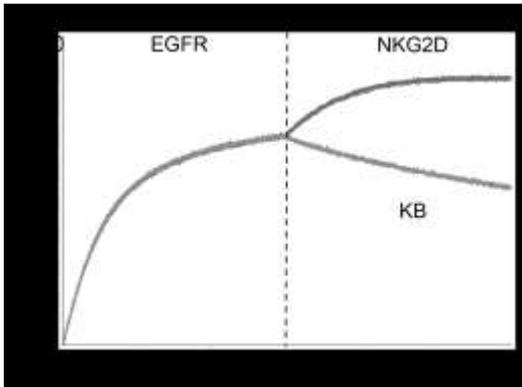

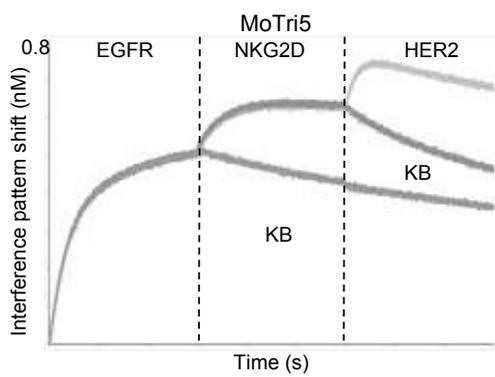

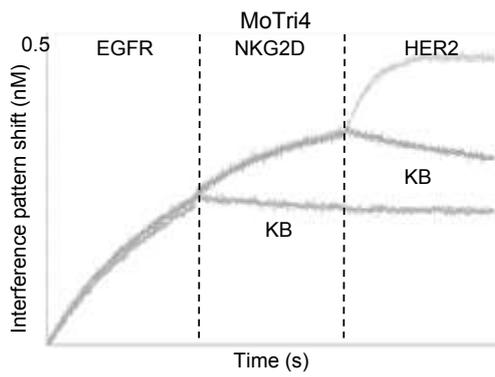

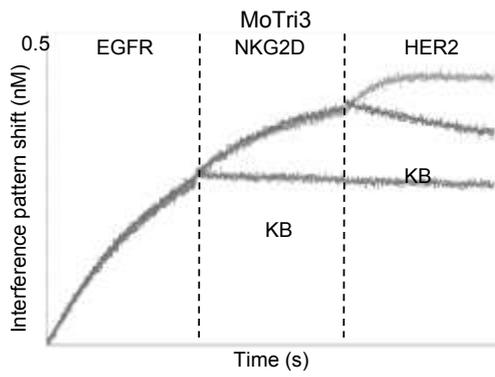

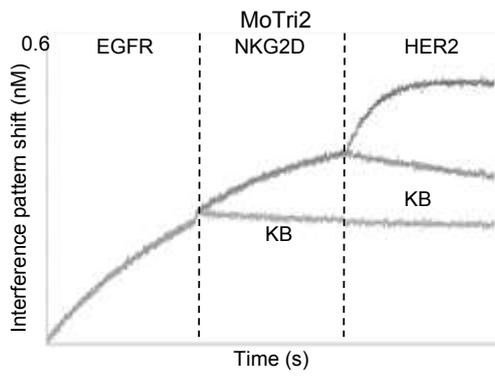

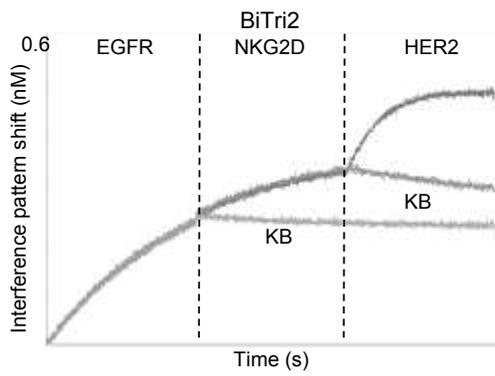

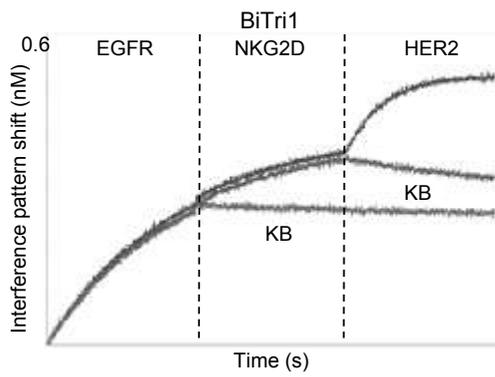

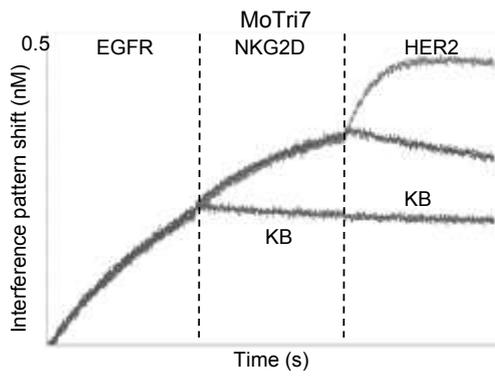

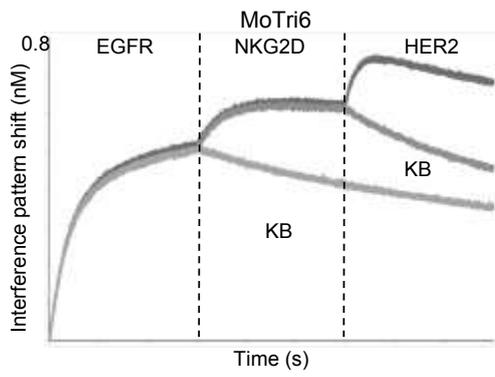

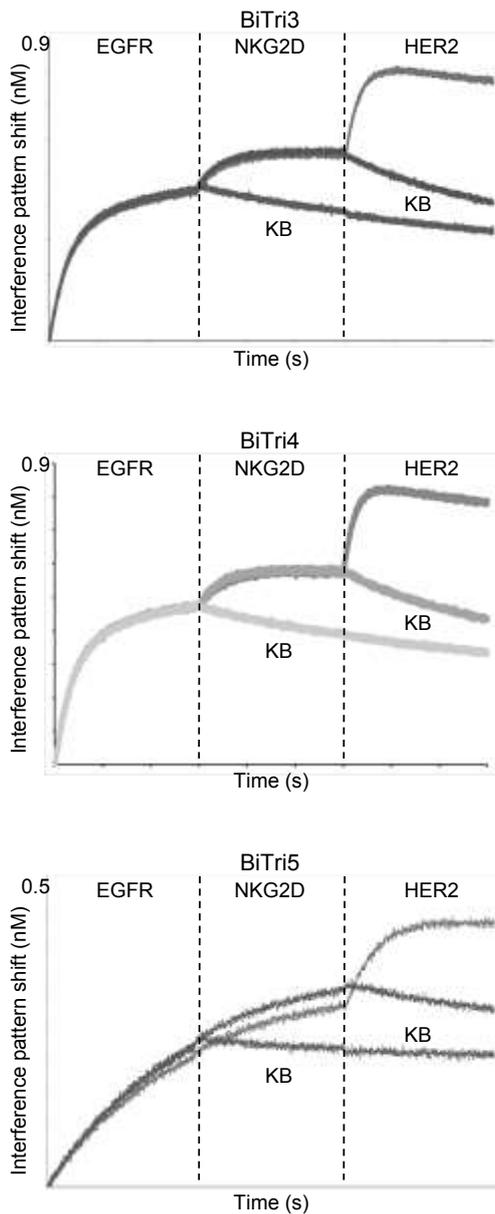

Fig. S3: Simultaneous binding of the antibody molecules used in this study via biolayer interferometry analysis. One armed monovalent bispecific, bivalent bispecific, monovalent trispecific and bivalent trispecific molecules were characterized. Consecutive binding against each antigen (EGFR, NKG2D and HER2) was measured at a concentration of 50 nM. Control measurements with kinetics buffer were conducted in parallel for each association step.

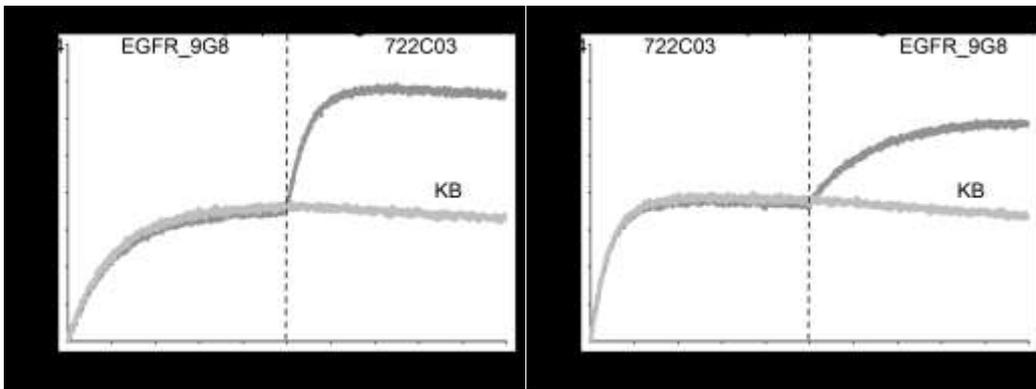

Fig. S4: Epitope binning experiments performed using Biolayer Interferometry. EGFR was captured via its histidine-tag on anti-Penta His (HIS1K) biosensors. Consecutive binding of one-armed control molecules (Ctrl1:9G8 and Ctrl4:722C03) is shown in both orientations.

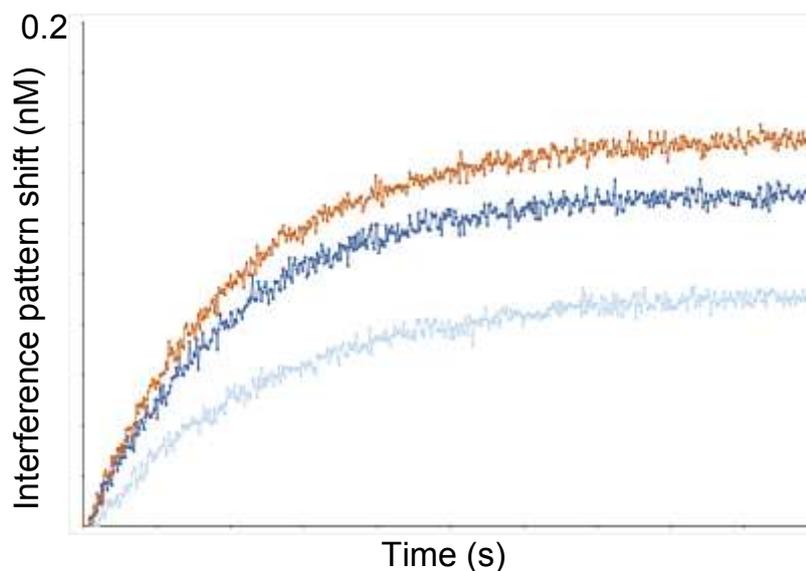

Fig. S5: Biolayer interferometry analysis to assess simultaneous binding capacities of one armed monovalent bispecific molecules comprising HER2-specific VHH grafted onto the SEED AG chain and EGFR-specific VHH 9G8 grafted onto light chain constant regions. Association of EGFR (50 nM) was measured (not shown), followed by a second association step of HER2 (50 nM). Brown: HER2-targeting VHH engrafted onto CH1 of the SEED AG chain and VHH 9G8 grafted onto CL λ . Light blue: HER2-specific paratope placed on AG chain (CH1) and 9G8 grafted onto CL κ . Dark blue: HER2-targeting single domain entity grafted onto the SEED AG chain (CH1) and 9G8 engrafted onto CL κ with ten amino acid flexible linker in between.

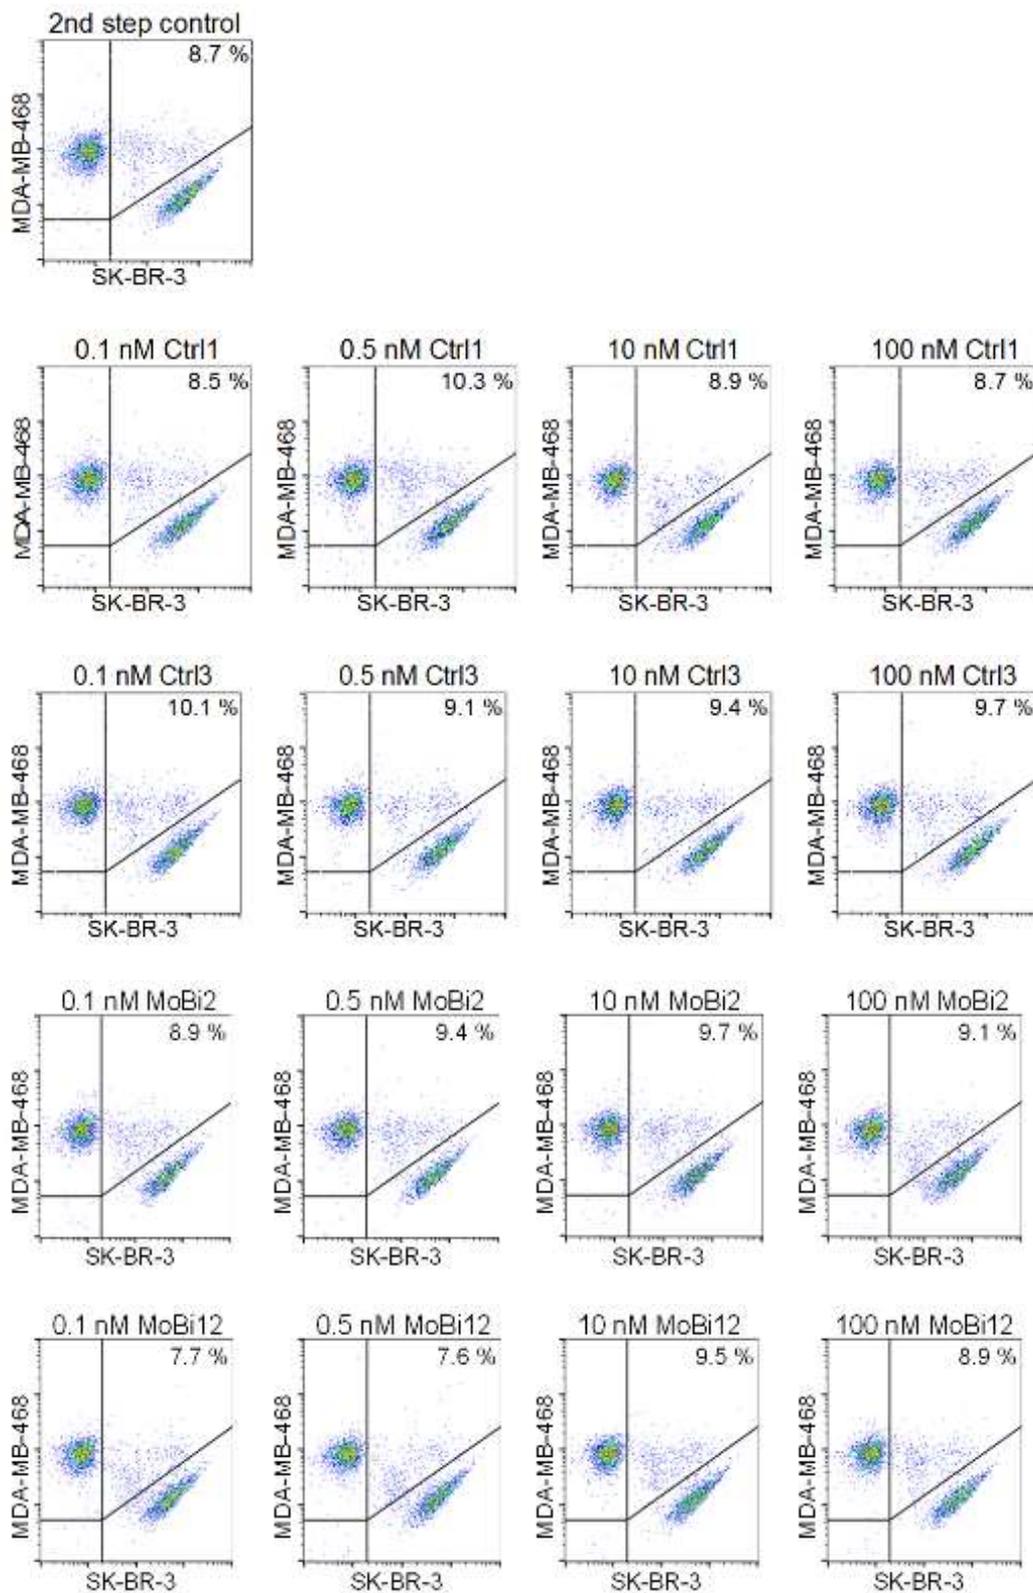

Fig. S6: Simultaneous cellular binding analysis of monovalent monospecific antibody Ctrl1 and Ctrl3, as well as monovalent bispecific antibody MoBi2 and MoBi12. Binding to EGFR-positive cell line MDA-MB-468 and Her2-positive cell line SK-BR-3 was assessed by flow cytometric analysis. Of note, MDA MB 468 was labelled with CellTracker™ Deep Red Dye and HER2-positive SK-BR-3 cells were labelled with CellTrace™ CFSE to allow for double positive fluorescence gating.

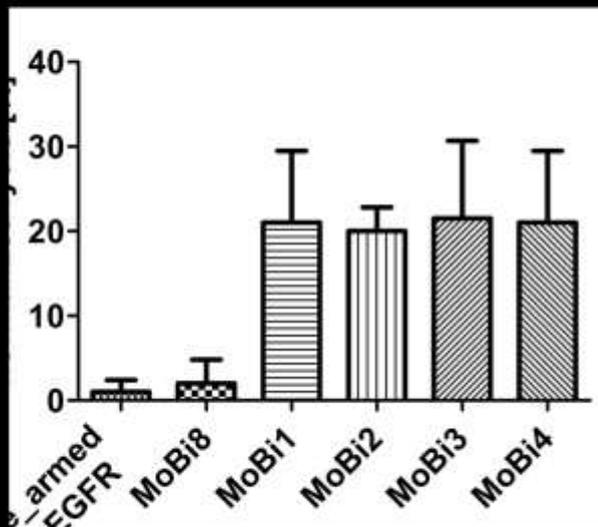

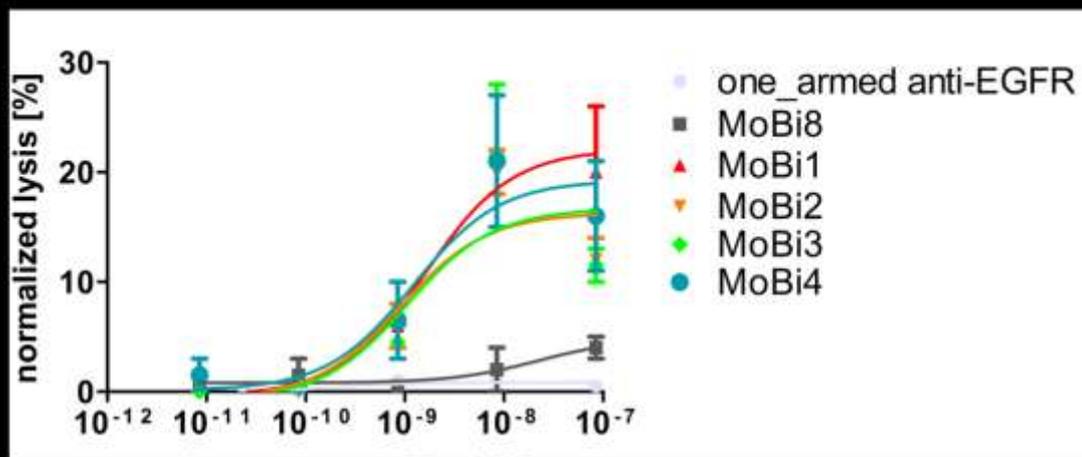

Fig. S7: NK cell-mediated tumor cell killing of EGFR-overexpressing cell line A431 using monovalent bispecific constructs and control molecules. All molecules used in this study were effector silenced (L234A, L235A, P329G). (A) Dose-response curve of one armed anti-EGFR (bright grey) and MoBi8 (EGFR AG:HER2 CL λ , dark grey) used as controls as well as EGFR and NKG2D engrafted molecules MoBi1 (EGFR AG:NKG2D CL κ , red), MoBi2 (EGFR AG:NKG2D CL λ , orange) MoBi3 (NKG2D AG:EGFR CL κ , green) and MoBi4 (NKG2D AG:EGFR CL λ , blue). (B) A431 tumor cell lysis mediated by bispecific NK cell redirection at a concentration of 10 nM. Cell lysis was normalized to staurosporine-mediated killing.

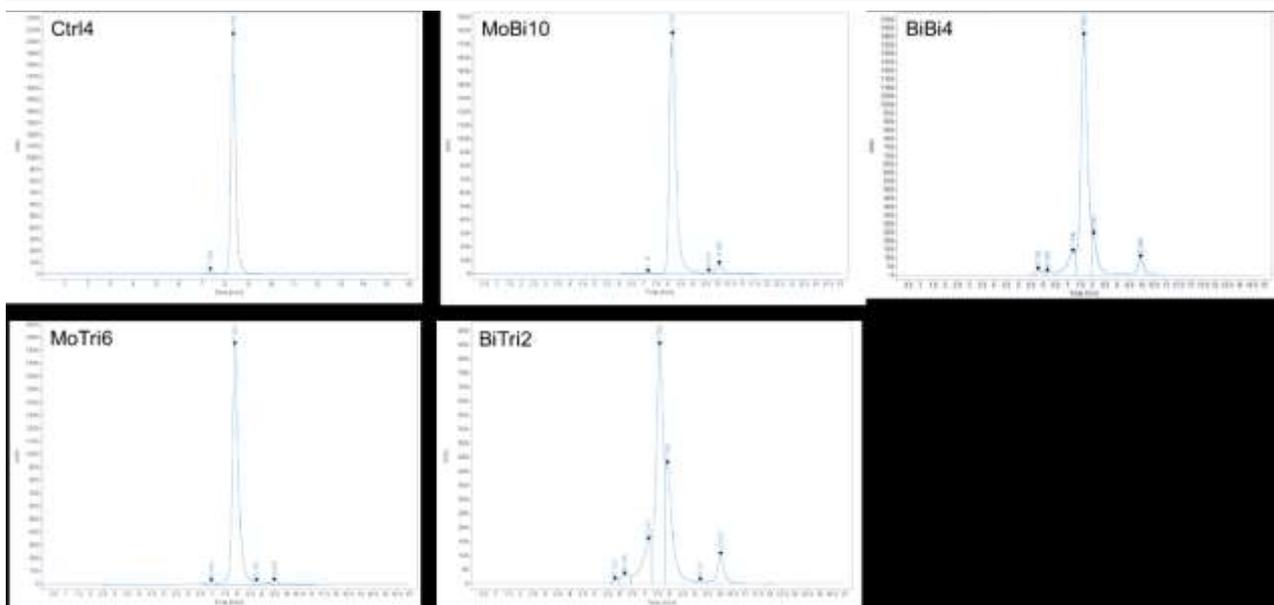

Fig. S8: Representative size exclusion chromatography profiles for selected control molecule Ctrl4, monovalent bispecific molecule MoBi10, bivalent bispecific VHH-derived IgG-like antibody BiBi4, monovalent trispecific entity MoTri6 and bivalent trispecific VHH-based IgG-like SEEDbody BiTri2.

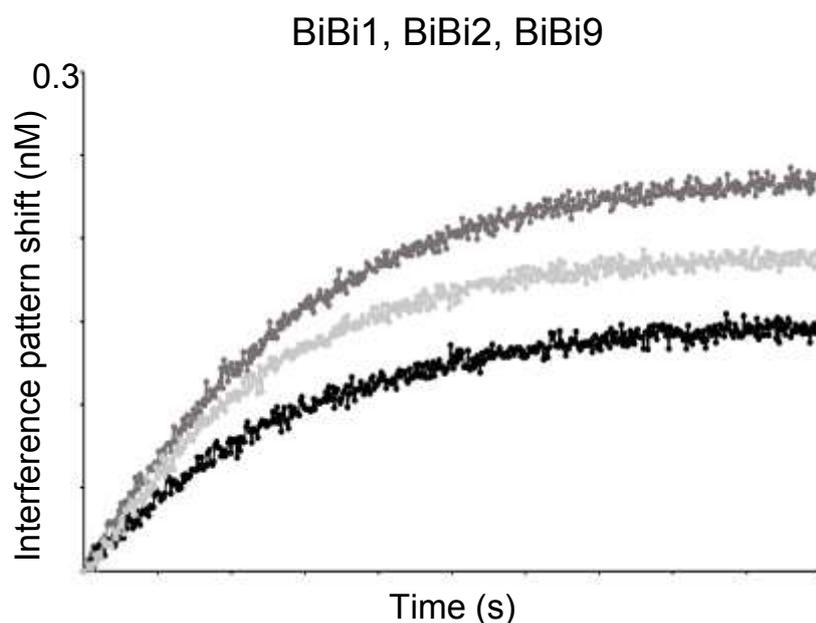

Fig. S9: Bi-layer interferometry analysis to assess binding of bivalent bispecific molecules to HER2 after association against EGFR. First association was performed against EGFR at a concentration of 50 nM (not shown), followed by a second association step with HER2 at 50 nM. Association against HER2 shown for bivalent bispecific BiBi7 (CL κ , black), BiBi2 (CL λ , dark grey) and BiBi9 (CL κ +10 aa linker, grey).

7.4 Affinity maturation of B7-H6 translates into enhanced NK cell-mediated tumor cell lysis and improved proinflammatory cytokine release of bispecific immunoligands via NKp30 engagement

Supplementary Material

Affinity maturation of B7-H6 translates into enhanced NK cell-mediated tumor cell lysis and improved proinflammatory cytokine release of bispecific immunoligands via NKp30 engagement

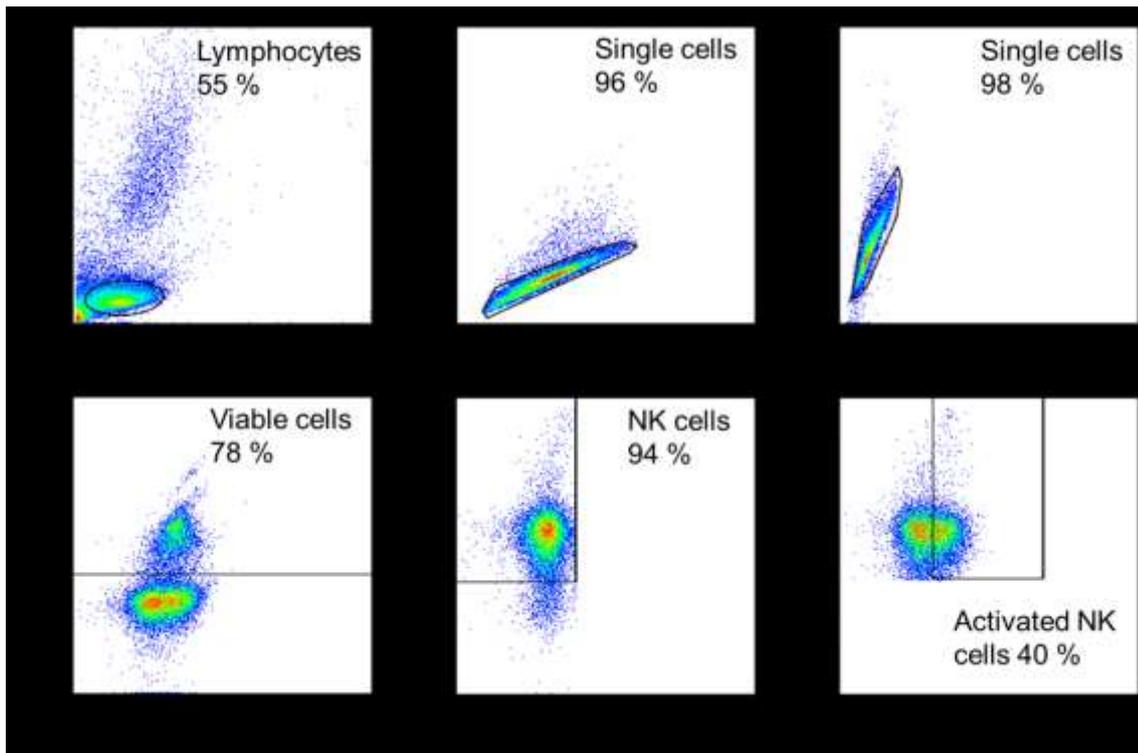

Fig. S1: Analysis of human NK cell activation by flow cytometry. Purified NK cells were incubated with A431 target cells (E:T = 5:1) for 24 hours at 37°C, stained with LIVE/DEAD™ Fixable Near-IR Dead Cell Stain and fluorochrome-conjugated anti-CD56 and anti-CD69 antibodies. FACS plots exemplarily demonstrate the gating strategy. Upper row: Side scatter (SSC) vs. forward scatter (FCS) for identification of single NK cells. Near IR and CD56 staining versus an unrelated channel was used for the identification of living CD56⁺ NK cells (lower row, left and middle plot) followed by gating on activated CD56⁺ CD69⁺ NK cells (lower row, right plot).

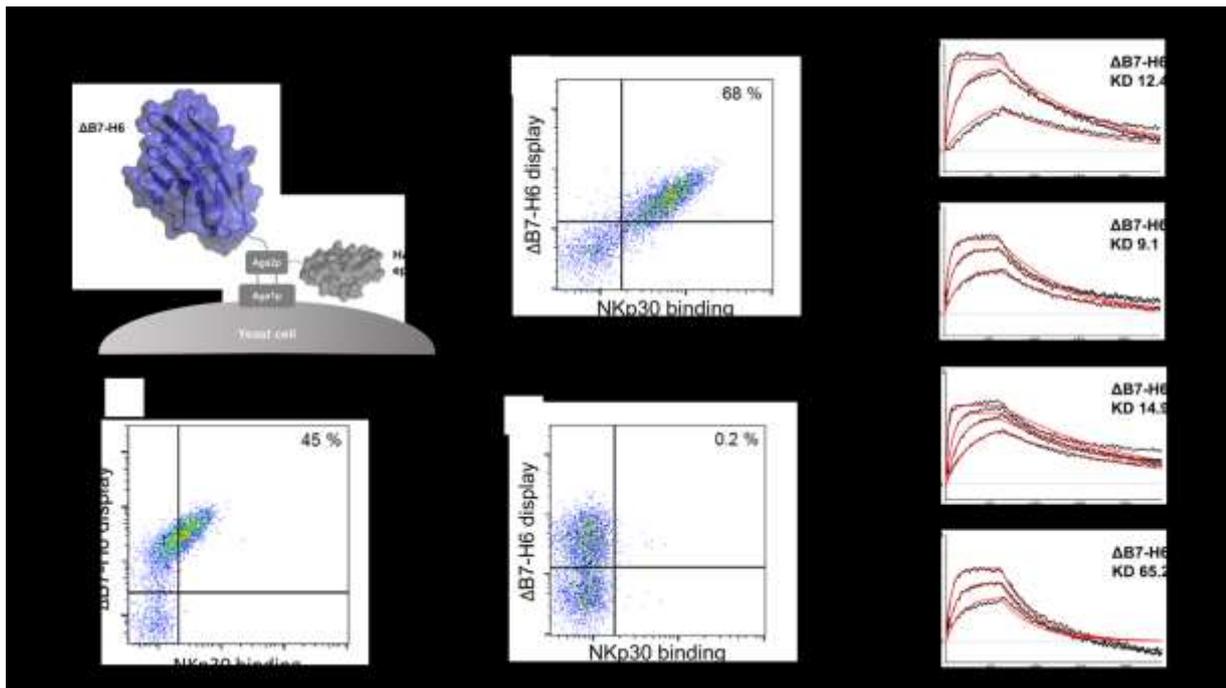

Fig. S2: Yeast surface display of Δ B7-H6 binding to NKp30 and analysis of the enrichment of affinity-enhanced Δ B7-H6 variants. (A) Schematic representation of Δ B7-H6 display by yeast surface display. For surface display, wildtype Δ B7-H6 as well as library candidates were expressed as fusion protein with Aga2p. A C-terminal HA tag was included for the detection of full-length Δ B7-H6 candidates. Simultaneous detection of Δ B7-H6 display and NKp30 binding at a concentration of 1 μ M (B), as well as library output of sorting round 3 (C) and wild-type Δ B7-H6 (D) stained with 50 nM NKp30. 10^7 yeast cells per sample were incubated simultaneously with pre-mixed anti-HA-PE, Penta-His Alexa Fluor 647 antibody and histidine-tagged human NKp30 solution for flow cytometric analysis. (E) BLI analysis of four leading affinity-optimized Δ B7-H6 immunoligand variants binding to NKp30.

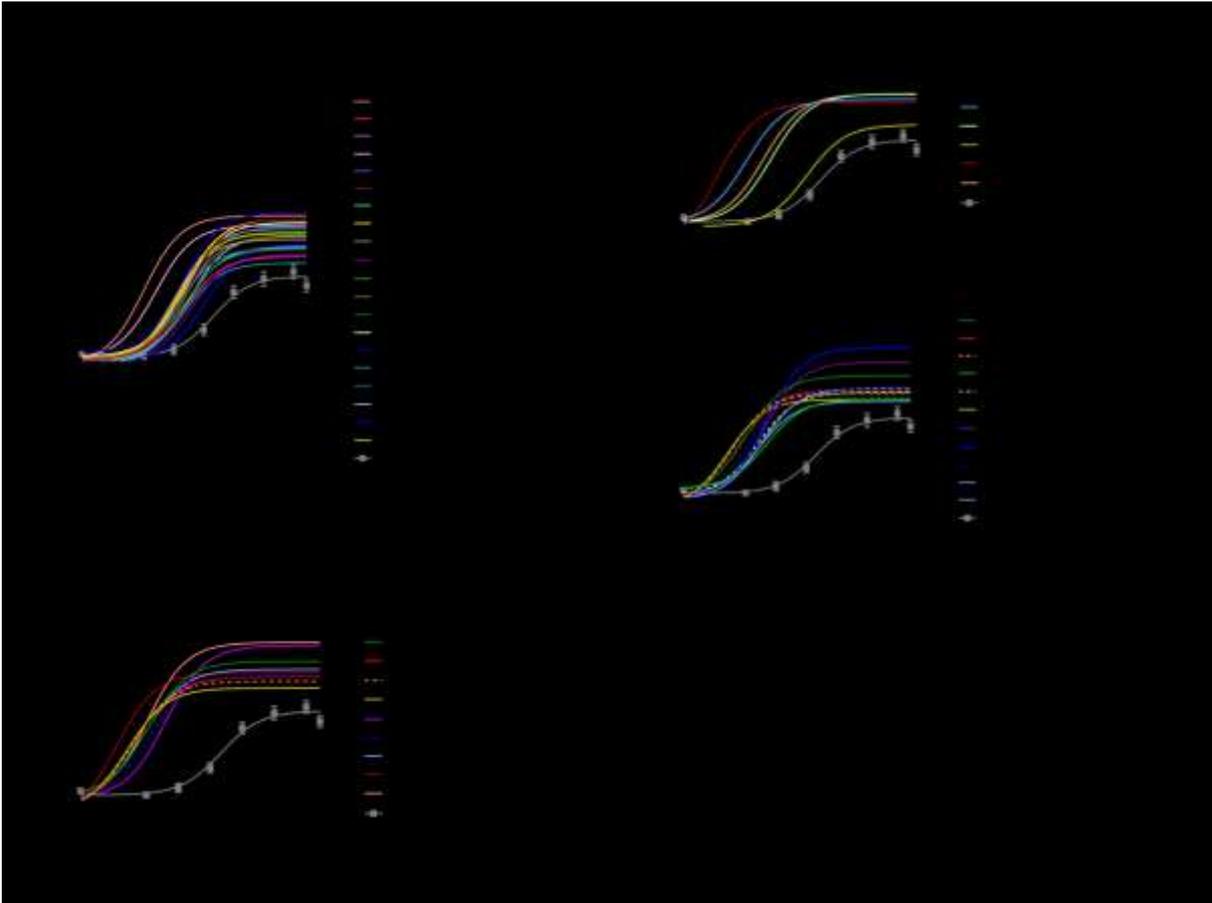

Fig. S3: EGFR-targeting, affinity-optimized Δ B7-H6 immunoligands exert potent killing of tumor cell line A431. Standard 4 h ^{51}Cr release assays were performed with human PBMCs and A431 cells at an E:T ratio of 80:1 to analyze concentration-dependent killing mediated by the 36 monovalent EGFR-targeting, affinity-matured Δ B7-H6 SEED-PGLALA NK cell engagers. Δ B7-H6 variants were compared to wild-type Δ B7-H6 NK cell engager (Δ B7H6 wt_hu225-SEED-PGLALA; grey line with grey squares) and a control molecule lacking Δ B7-H6, but still binding one-armed (oa) to EGFR via the humanized Cetuximab Fab (oa_hu225-SEED-PGLALA; dotted black line). To allow comparison of the results obtained from different donor PBMCs, data of each experiment were normalized using Cetuximab induced lysis at saturating concentration as 100 % and oa_hu225-SEED-PGLALA induced lysis as 0 %. B7-H6 variants are grouped in graphs according to their KD values with candidates having less than 5-fold improved NKp30 binding shown on the upper left, variants with 5- to 10-fold improved binding shown on the upper right and variants with more than 10-fold improved NKp30 binding shown on the lower right. Selected Δ B7-H6 candidates are in bold and the leading 9 candidates are summarized in the graph on the lower right. Data shown in all graphs represent normalized means \pm SEM of individual experiments with different donors.

Table SI: Biochemical and biophysical characterization of immunoligands based on affinity-optimized Δ B7-H6 variants.

Letter of Acceptance

Dear Authors,

I'm pleased to confirm that your chapter **Display Systems and Libraries of Antibodies (phage, yeast, ribosome, mammalian)**, authored by Janina Klemm, Lukas Pekar, Simon Krahl and Stefan Zielonka, was accepted for publication in the textbook *Rüker & Wozniak-Knopp (eds), Introduction to Antibody Engineering*. The book is currently in preparation; its publication is planned for Q3 2020.

With best wishes,
Silvia Herold

Yeast Surface Display in Combination with Fluorescence-activated Cell Sorting Enables the Rapid Isolation of Antibody Fragments Derived from Immunized Chickens

Julius Grzeschik, Desislava Yanakieva, Lukas Roth, Simon Krahl, Steffen C. Hinz, Adrian Elter, Tina Zollmann, Gerhard Schwall, Stefan Zielonka, and Harald Kolmar*

Dedicated to Professor Hans Günter Gassen on the occasion of his 80th birthday.

Yeast surface display emerged as a viable tool for the generation of human and murine monoclonal antibodies. This platform technology enables the careful definition of selection conditions, the potential for high-throughput screening, as well as the isolation of antibodies recognizing predefined epitopes. In this study, the applicability of yeast surface display in combination with fluorescence-activated cell sorting (FACS) for the isolation of antigen-specific chicken-derived antibodies is demonstrated. To this end, yeast-displayed recombinant antibody libraries from splenic mRNA of chickens immunized with epidermal growth factor receptor (EGFR) and human chorionic gonadotropin (hCG) were constructed as single chain variable fragments (scFv) by overlap extension polymerase chain reaction. A large number of antigen binding scFvs were readily isolated in a convenient screening process. Target-specific scFv-Fc molecules were produced as soluble proteins and more extensively characterized by confirming specificity, thermostability and high affinity. Essentially, we demonstrated the biotechnological applicability of binders directed against both antigens via specific cellular binding for EGFR and in the context of a lateral flow test by utilizing hCG-binding scFvs as capturing antibodies for pregnancy detection. Altogether, the described strategy using yeast surface display expands the repertoire of display methods for the isolation of antibodies resulting from chicken immunization campaigns.

1. Introduction

Antibodies and antibody-based formats (Fab, scFv) have become some of the most successfully and frequently used biomolecules both for biotechnological and biomedical purposes. As of March 2017, more than 58 antibodies were clinically available for treatment of various diseases and monoclonal antibodies (mAbs) represented 25% of the biopharmaceutical market, which on its side took about 25% of the global pharmaceutical market.^[1] The huge success of antibodies is based on their function as versatile ligands which target various antigens with high-affinity and selectivity. This makes them suitable for therapeutic applications like treatment of cancer, inflammatory, and autoimmune diseases, as well as for analytical and diagnostic purposes such as various formats of immunoassays: Western Blot,^[2] enzyme-linked immunosorbent assay (ELISA),^[3] and lateral flow tests.^[4]

Antibody discovery can be performed using immunized animals, followed by surface display screening techniques, e.g., phage display,^[5] yeast surface display,^[6]

ribosomal display,^[7–9] mammalian display.^[8,10] While originally immunized mice have been primarily used as a source of immunoglobulin (Ig) repertoires, today also other animals such as camelids, sharks, and chickens have been chosen as hosts for the generation of target-specific variable domains.^[11] These animals bring the advantages of distinct antibody formats (e.g., heavy-chain-only antibodies from camelids and cartilaginous fish^[12]) and a potentially high immunogenicity of a particular antigen due to the phylogenetic distance from humans, which makes them useful for the generation of antibodies recognizing conserved epitopes on mammalian molecules.^[13] Moreover, the peculiar Ig gene diversification mechanism in chickens that is based on somatic gene conversion events allows the facile generation of antibody libraries by using single primer pairs for the heavy and light chain, respectively, enabling one-step PCR amplification of the variable domain gene repertoire.^[14–18]

While chicken V-gene sequences are theoretically uniform and humanizable,^[19,20] chicken CDR3 repertoire differs significantly from those of human and mouse. CDR3 loops of chickens tend to be longer and have much higher cysteine content, which suggests the presence of noncanonical disulfides, leading to increased CDR stability and complexity.^[21]

To date, multiple chicken-derived single-chain variable fragments (scFvs) against various targets have been successfully generated and characterized using phage display technology.^[13,22–24] In this process, the variable domains of the heavy and light chains are amplified from the chicken immunoglobulin repertoire and randomly connected via short polypeptide linker sequences, resulting in a high-diversity gene library of scFvs with antigen-binding properties.^[22,25] In order to identify high affinity antigen binders, scFvs are genetically fused to the coat protein of filamentous bacteriophage and displayed on the surface of the phage particles.^[26,27] Selection of antigen-specific binders from phage libraries is performed through a multi-step in vitro panning procedure, consisting of binding to the immobilized antigen, washing, elution, and enrichment of phages in *Escherichia coli*, repeated in multiple cycles.^[28]

Alternatively, yeast surface display can be employed as a platform for the screening and isolation of antibody fragments. This strategy combines the benefits of online and real-time analysis of the library candidates by fluorescent-activated cell sorting (FACS)^[29] with the advantages of an eukaryotic expression apparatus and unfolded protein response for degradation of misfolded or aggregated proteins.^[30,31] For the generation of yeast cell libraries, the protein of interest is genetically fused to a cell wall-anchored protein. Most commonly used is the α -agglutinin-system, where the antibody DNA sequence is fused to the gene of α -agglutinin II subunit (Aga2p).^[6] Upon expression in the yeast cell, the fusion protein is secreted and forms two disulfide bonds with the α -agglutinin I subunit (Aga1p), anchored through its C-terminal glycosylphosphatidylinositol (GPI) attachment signal to the cell wall (Figure 1). High-throughput selection of high affinity binders can be performed by multiple rounds of FACS, leading to an enrichment of target binding cells.^[4]

We reasoned that microbial display in combination with controlled screening by FACS sorting with online monitoring of binding capabilities might facilitate isolation of affine, stable and specific binders of chicken-derived antibodies via accurate setting of screening conditions and monitoring of binding capabilities of each clone at a given target concentration in solution. To this end we immunized two specimens with epidermal growth factor receptor (EGFR) and human chorionic gonadotropin (hCG), respectively, both of pharmaceutical or diagnostic relevance.

EGFR is a transmembrane receptor tyrosine kinase, stimulated by growth factors (transforming growth factor (TGF)- α and EGF), involved in the regulation of cellular differentiation and proliferation.^[32] It is overexpressed on many tumor cells and thus has emerged as a promising target for cancer therapy.^[33] Anti-EGFR antibodies cetuximab (Erbixux) and panitumumab (Vectibix) build up to date the foundation of metastatic colorectal cancer treatment.^[34]

hCG is a glycoprotein hormone, synthesized by the syncytiotrophoblast cells of the placenta.^[35] Also referred to as "pregnancy hormone", it can be detected as early as six days after conception,^[36] thus being used as the earliest indication of pregnancy. The generation of specific monoclonal antibodies against the beta subunit of hCG has enabled simple and very sensitive detection of the hormone in the urine, leading to development of multiple pregnancy tests well suited as well as for the public as for healthcare professionals.^[37]

In this study we report to our knowledge the first application of yeast surface display in combination with FACS for facile and efficient generation of high affinity chicken-derived binders against model target proteins EGFR and hCG with therapeutic or diagnostic relevance. Both, anti-EGFR and anti-hCG binders show high affinities in the single-digit nanomolar range determined via Bio-Layer Interferometry. The functionality of the generated chicken-derived antibody formats was proven with the aid of immunofluorescent staining experiments (EGFR) and lateral flow tests (hCG) showing comparable results to the commercial available constructs.

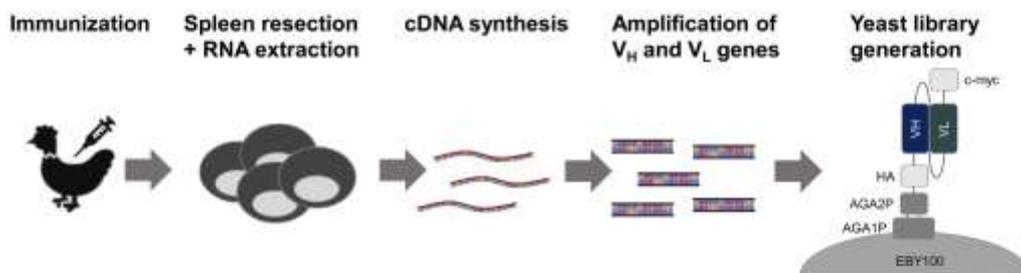

Figure 1. Workflow for the generation of chicken-derived antibody fragments from immune evolved repertoires. Chickens were immunized separately with two different antigens, EGFR and hCG. Spleen cells were isolated followed by extraction of total RNA and cDNA-synthesis. Afterwards cDNA was used as template for the amplification of variable regions. Resulting scFv molecules were presented on the yeast surface as Aga2p fusions with a N-terminal HA-tag as well as C-terminal cMyc-tag for the detection of antibody surface expression.

2. Experimental Section

2.1. Chicken Immunization

Two different antigen cocktails were used for chicken immunization: One chicken (*Gallus gallus domesticus*) was immunized with human EGFR (extracellular domain, produced and purified in house) and another specimen with a cocktail of EGFR and hCG (BBI Solutions P111-0). The whole immunization process was performed at Davids Biotechnologie (Regensburg, Germany). Briefly, two pathogen-free adult laying hens were immunized by injecting intramuscularly 150 µg of the respective antigens using AddaVax (InvivoGen) as vaccine adjuvant. After initial injection, the birds received boosters after 2, 4, 5, and 8 weeks. Immune response to the target antigens was determined after 5 weeks by monitoring their antigen-specific titer^[38] using ELISA. Experimental procedures and animal care were in accordance with EU animal welfare protection laws and regulations. After 9 weeks both animals were sacrificed followed by isolation of total splenic RNA using TriFast reagent (VWR).^[39]

2.2. Yeast Strains, Media, and Reagents

For yeast surface display the *Saccharomyces cerevisiae* strain EBY100 was utilized.^[6] YPD medium was prepared using 20 g L⁻¹ dextrose, 20 g L⁻¹ tryptone, and 10 g L⁻¹ yeast extract. SD-CAA medium was composed of 8.6 g L⁻¹ NaH₂PO₄ × H₂O, 5.4 g L⁻¹ Na₂HPO₄, 1.7 g L⁻¹ yeast nitrogen base without amino acids, 5 g L⁻¹ ammonium sulphate, 5 g L⁻¹ Bacto Casamino Acids, and 20 g L⁻¹ dextrose. SG-CAA medium was prepared identically except for the substitution of dextrose sugar with galactose. Phosphate-buffered saline (PBS) contained 8.1 g L⁻¹ NaCl, 1.13 g L⁻¹ Na₂HPO₄, 0.75 g L⁻¹ KCl, and 0.27 g L⁻¹ KH₂PO₄.

2.3. Yeast Library Construction

After RNA extraction, cDNA-synthesis was performed using 50 µl RNA extract, 10 µl random hexamer primers (50 ng µl⁻¹), 10 µl 50 µM dNTPs, 30 µl H₂O, 40 µl 25 mM MgCl₂, 20 µl 10× RT-buffer, 20 µl 0.1 M DTT, 10 µl RNase OUT, and 10 µl SuperScript III reverse transcriptase (all components from SuperScript III First-Strand Kit, Thermo Fisher Scientific). The mixture was incubated for 5 min at 25 °C followed by incubation for 60 min at 50 °C and a subsequent inactivation step at 85 °C for 5 min. Afterwards, 1 µl RNAaseH was added and the solution was incubated for 20 min at 37 °C. The synthesized cDNA was stored at -20 °C. Variable antibody regions were amplified from cDNA in two separate PCR reactions using Taq Polymerase (NEB) in a reaction volume of 100 µl. For each animal and chain 6 different reactions were prepared using 3 µl cDNA. Amplification of V_H genes was performed using the primer pair VH_gr_up/VH_SOE_lo, for V_L genes with VL_SOE_up/VL_gr_lo, respectively. Primer sequences are listed in Table S1, Supporting Information. For all reactions the following conditions were set: 95 °C for 30 s, 30 cycles of 20 s at

95 °C, 30 s at 55 °C, and 30 s at 68 °C, followed by 68 °C for 5 min. PCR products were purified via Wizard SV Gel and PCR Cleanup System (Promega). Assembly of scFv constructs including (Gly₃Ser)₃ linker sequences and overlaps up- and downstream of the NheI and BamHI restriction sites of the pCT-plasmid^[6] was performed via fusion PCR under the following conditions: 200 ng of each V_H and V_L domains were amplified using Taq polymerase for 15 cycles without addition of primers with an elongation time of 50 s. Subsequently, 15 PCR cycles were performed after addition of the primer pair VH_gr_up/VL_gr_lo. The pCT vector used for gap repair cloning and surface presentation of scFv variants was digested with NheI and BamHI and purified via Wizard SV Gel and PCR Cleanup System. Library generation in *S. cerevisiae* EBY100 cells was performed according to Benatui and colleagues.^[40]

For large-scale yeast library generation 4 µg of digested pCT plasmid was mixed with 12 µg of insert DNA for each electroporation reaction. In total, 14 transformation reactions per library were performed. Yeast cells were transferred to SD-CAA medium and incubated overnight at 30 °C and 180 rpm. Determination of library sizes was performed via analysis of serial dilution platings after 3 days.

2.4. Yeast Library Screening

Induction of gene expression and surface presentation was performed by inoculation of SG-CAA medium to a cell density of 1 × 10⁷ cells ml⁻¹ followed by incubation at 30 °C and 180 rpm for 24 h. Prior to labeling the libraries for sorting, cells were washed two times with BPBS (PBS + 0.1 % bovine serum albumin (BSA)). Antigen staining was performed either by employing biotinylated hCG using EZ-Link Sulfo-NHS-LC-Biotin (Thermo Fisher Scientific), Penta-His Alexa Fluor 647 Conjugate antibody (Qiagen) for his-tagged EGFR or anti-Human IgG Fc-PE conjugate (Affymetrix eBioscience) for Fc-tagged EGFR (R&D Systems). Labeling steps were performed for 30 min with 1 × 10⁷ cells per 20 µl on ice. After incubation with the target protein cells were washed two times with BPBS followed by staining for surface presentation using anti-cMyc antibody (produced in-house; undiluted) or anti-c-myc-Biotin antibody (Miltenyi Biotec; 1:50 diluted). Final staining steps were performed using an anti-mouse IgG antibody APC conjugate (Affymetrix eBioscience, diluted 1:50), Penta-His Alexa Fluor 647 Conjugate antibody (diluted 1:20), Streptavidin conjugated to APC or PE (Affymetrix eBioscience; diluted 1:75) or anti-Human IgG Fc PE conjugate (diluted 1:75). After washing with BPBS library cells were prepared for flow cytometry sorting. Library screening was performed on a BD Influx cell sorter following the instructions of the manufacturer and analyzed via BD FACS Software v1.0. Sorted cells were subsequently transferred to SD-CAA medium for further incubation at 30 °C for 2 days. The second screening round was performed with at least a 10-fold excess of cells collected in the previous round to ensure coverage of the enriched populations. Plasmid DNA from antigen-binding populations was isolated via Zymoprep Yeast Plasmid Mini-prep (Zymo Research) and transformed into Top 10 competent *E. coli* cells for plasmid rescue and sent out for sequencing with pCT_seq_lo and pCT_seq_up oligonucleotides. Mapping of hCG epitopes by flow cytometry was

performed after induction of cells resulting from R2.1 using an anti-hCG beta antibody (Fitzgerald; monoclonal; 10-C25D; diluted 1:200) or biotinylated human TSH (R&D systems).

2.5. Expression of Selected scFv-Fc Variants

Reformatting of the identified scFv variants was performed by genetic fusion to human IgG1 Fc region encoded in the mammalian expression vector pEXPR-IBA42. After introducing flanking *NheI* and *ApaI* sites for ligation into the linearized plasmid, constructs were sequenced followed by transient transfection of Expi293FTM cells using polyethylenimine (Polysciences) following the instructions of the manufacturer (Thermo Fisher Scientific). After 5 days culture supernatants were harvested, sterile-filtered (0.22 μm Filteropur S 0.2, Sarstedt) and purified using HiTrap Protein A HP columns (GE Healthcare) in combination with an AKTA purification system (GE Healthcare). Buffer exchange was carried out via dialysis against PBS using a membrane with a MWCO \approx 14 kDa. Aggregate formation was analyzed by analytical size exclusion chromatography. Therefore, a TSKgel SuperSW3000 column (4.6 \times 300 mm, Tosoh Bioscience LLC) and an Agilent HPLC system was used.

2.6. Binding Kinetics

Binding kinetic measurements were performed on Octet RED96 system (FortéBio) at 30 °C and 1000 rpm agitation in 200 μl . For EGFR binders scFv-Fc molecules were loaded on anti-human Fc biosensors (AHC) at 3 $\mu\text{g ml}^{-1}$ in kinetics buffer (KB; PBS, 0.1% Tween 20 and 1% BSA) for 90 s. For analysis of hCG binders biotinylated hCG was loaded on SAX tips at 1.5 $\mu\text{g ml}^{-1}$ for 120 s. Afterwards, tips were transferred to KB for 60 s for sensor rinsing. Subsequently, association of varying concentrations from 100 nM to 3.125 nM of EGFR or hCG-binding scFv-Fc was measured for 300 s followed by dissociation for 300 s in KB. In each experiment, a negative control was implemented by incubating the captured scFv with unrelated antigen or incubating tips loaded with unrelated antigen with soluble scFv-Fc for analysis of anti-hCG moieties. Data fitting and analysis was carried out with FortéBio data analysis software 9.1 using a 1:1 Langmuir binding model after subtraction of control curve after Savitzky-Golay filtering.

2.7. Thermal Shift Assay

Experiments were performed in triplicates on a BioRad96CFX RT-PCR detection system with 0.5 °C/30 s to 99 °C. T_m values were collected from melting curves using the corresponding BioRad analysis software. All reactions were performed in PBS, pH 7.4 in presence of 0.1 mg ml^{-1} protein and SYPRO Orange (diluted 1:800, Sigma-Aldrich).

2.8. Lateral Flow Test

Anti-hCG chicken scFv fragments were tested for application in a classical lateral flow test setup using Hi-FlowTM Plus HF120

nitrocellulose membranes (HF12002XSS, Merck) and a mouse anti-hCG 40 nm gold conjugate (BA.HCG40, BBI Solutions). As positive control an anti-beta hCG monoclonal capture antibody (01041131C, BBI Solutions) was used.

Test line solutions containing 0.25 mg ml^{-1} anti-hCG specific capture antibody domains in 10 mM MES (pH 6.5) and control line solution containing 0.25 mg/ml goat anti-mouse capture antibody (M8890, Merck) in 10 mM MES (pH 6.5) were striped 4-times onto membranes using a Kinematic Matrix 1600 Reagent Dispensing Module (bed speed: 6 cm s^{-1} , pump: 1 $\mu\text{l cm}^{-1}$) to yield 0.5 μg capture protein per strip. Membranes were dried 2 h at 37 °C.

Anti-hCG gold conjugates (OD 2) in 5% (w/v) trehalose were applied onto glass fiber conjugate pads (GFDX203000, Merck) and dried o/n at RT.

Membranes and conjugate pads were assembled with cellulose sample pads (CFSP223000, Merck; treated with 10 mM Tris-HCl pH 8.2, 1% (w/v) Tween 20, 0.75% (w/v) BSA), and absorbent pads (CFSP223000, Merck) into a classical lateral flow test setup.

Chicken scFv functionality in lateral flow tests was analyzed by either hCG positive (200–400 mIU mL^{-1}) or negative human urine (Biochemical Diagnostics Inc.) or a hCG concentration series spiked in synthetic urine (S-020, Cerilliant).

2.9. Cellular Binding

Human cancer cell lines MDA-MB-468 and MCF-7 Cells were obtained from the American Type Culture Collection and maintained according to standard culture conditions (37 °C, 5 % CO₂, 95 % humidity) using recommended media formulations. Both cell lines were maintained in RPMI-1640 (Life Technologies) supplemented with 10% FBS, 2 mM L-glutamine and 1 mM sodium pyruvate (both Life Technologies).

Prior to analysis of cellular binding both cell lines were trypsinized from the culture flask and then spun down. Cells were washed three times with 1% BPBS followed by incubation with the respective scFv-Fc constructs (100 μl ; 100 nM scFv-Fc in 1% BPBS) for 1 h. Consequently, cells were washed and incubated with the fluorescently labeled secondary antibody (10 $\mu\text{g mL}^{-1}$; Alexa Fluor 488-conjugated AffiniPure goat anti-human IgG, Fc γ fragment specific (Jackson Immuno Research)) for 1 h, washed again and stained with propidium-iodide (1:200 dilution in 1% BPBS). Finally, cells were analyzed using a Guava EasyCyte HT flow cytometer device (EMD Millipore).

3. Results

3.1. Chicken Immunization and Yeast Library Generation

In order to test the suitability of yeast surface display in combination with FACS for the selection of chicken-derived antibodies resulting from animal immunization, two immunization campaigns utilizing the antigens EGFR and hCG were started. Serum IgY titer analysis of both specimens after 35 d indicated a positive immune response against both antigens

(Figure S1, Supporting Information). cDNA was prepared utilizing total RNA from spleen tissues via reverse transcription.

V_L and V_H genes were amplified separately by PCR using synthesized cDNA as template as well as primer sequences already reported for the generation of phage display libraries from chicken antibody repertoires.^[41–44] Afterwards, the amplicons coding for V_L and V_H domains were randomly connected via a flexible (Gly₃Ser)₁ linker using fusion PCR resulting in the combinatorial scFv gene repertoire. For both animals, individual scFv yeast libraries were generated by a homologous recombination-based process referred to as yeast gap repair cloning (Figure 1). This resulted in two libraries with calculated library sizes of approximately 5×10^8 (EGFR) and 4×10^8 (EGFR/hCG) unique clones, respectively. Analysis of cMyc tag labeling intensity after induction of library cells with galactose revealed a surface presentation of >50 % of yeast cells for both libraries (Figure S2, Supporting Information).

3.2. Yeast Library Screening

The libraries were screened separately by FACS for binders of recombinant human EGFR and human hCG protein. Target binding was identified by indirect antigen fluorescence staining according to section 2.4. scFv surface display levels were analyzed simultaneously by cMyc tag labeling. Furthermore, negative controls in absence of antigen were performed to confirm only antigen positive cell populations being considered in the gating strategy. As shown in Figure 2 we were able to enrich for antigen-positive populations within two consecutive screening rounds by employing 1 μ M or 500 nM antigen, for EGFR and hCG, respectively. Moreover, no binding against secondary detection reagents was observed. Both sorts were repeated with decreased concentrations of 1 nM for EGFR and 5 nM for hCG, respectively to enable the isolation of high-affinity scFvs. FACS analysis after library sorting showed for both campaigns nearly exclusively antigen binding populations (Figure S3, Supporting Information).

In addition to enriching of antigen-binding populations, yeast surface display also allows for facile epitope analysis of enriched library candidates.^[45] Related to this, hCG is a heterodimeric

protein comprising a generic alpha subunit present in many hormones as well as a hCG-specific beta subunit. In order to estimate the fraction of hCG-specific variants targeting the beta subunit, the antigen enriched population after sorting round II was analyzed for binding to TSH (Thyroid-stimulating hormone) that shares the same alpha subunit with hCG. This indicated a relative amount of approximately 40% of cells displaying scFvs most likely binding the hCG-specific beta subunit (Figure S4, Supporting Information).

To evaluate potential sequence patterns and to confirm the presence of a sufficient diversity after library sorting, plasmid DNA from both enriched libraries was sent out for sequencing. With respect to EGFR binders unique amino acid sequences were identified in 70 out of 71 analyzed clones for heavy chain genes and 73 out of 73 clones for the light chains (Figure S5, Supporting Information). Akin to this, sequencing of hCG binders resulted in 74 out of 78 unique clones for heavy chain variants and 66 out of 74 unique variants for light chain genes, respectively. However, in both sequencing approaches the enrichment of several distinct heavy chain CDR3 sequences allowed for the assignment into different clustered sequence patterns that have been accumulated in the sorting process. Furthermore, the sequence analysis revealed the presence of several clones bearing noncanonical disulfide patterns in the V_H domain, which can be divided into: Type 1, containing two cysteines in the heavy chain CDR3 loop, type 2 with no incorporated cysteine residues and type 3, containing one cysteine in the CDR1 plus one cysteine in the CDR3.

3.3. Generation of scFv-Fc Variants and Characterization

From both enriched populations three clones were chosen for reformatting based on their CDR3 sequence abundance and expressed as scFv-Fc fusion proteins in Expi293F cells, termed E1-E3 for EGFR binders and H1-H3 for hCG binders. After production and purification using Protein A columns, the proteins were assessed by SDS-PAGE, indicating bands with the expected molecular weight of approximately 52.5 kDa as well as a high purity (Figure S6, Supporting Information). Thermal stabilities were determined by differential scanning fluorimetry

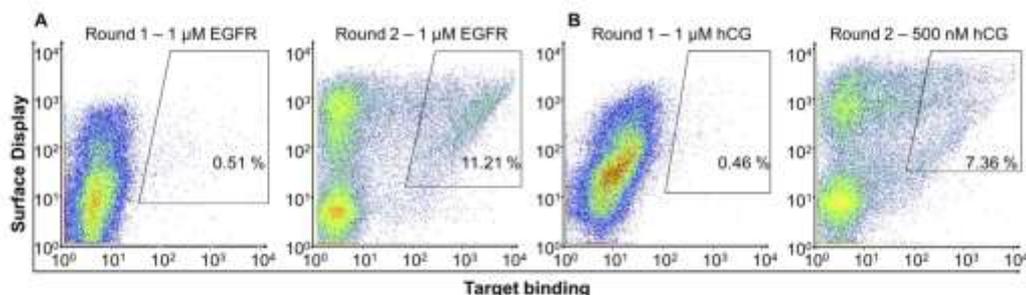

Figure 2. Chicken-derived scFv library screening against EGFR (A) and hCG (B). Sorting gates, percentages of cells in the respective gate and target concentrations are shown. Yeast cells were labeled for simultaneous detection of full-length scFv expression using cMyc-tag staining as well as for antigen-binding. In each round cells in the sorting gate were isolated, grown and induced for the second round of selection. After the second screening round clones of the enriched binding populations were sequenced.

Table 1. Kinetic parameters of chicken-derived scFv-Fc determined using bio-layer interferometry.

scFv-Fc variant	K_D [nM]	k_{on} [$M^{-1} s^{-1}$]	k_{off} [s^{-1}]
H1	1.2 ± 0.01	$1.8 \times 10^6 \pm 1.5 \times 10^6$	$2 \times 10^{-3} \pm 1.2 \times 10^{-3}$
H2	4.2 ± 0.05	$5 \times 10^5 \pm 7.3 \times 10^5$	$1.2 \times 10^{-3} \pm 1.9 \times 10^{-3}$
H3	6.8 ± 0.1	$4.2 \times 10^5 \pm 6.2 \times 10^5$	$2.6 \times 10^{-3} \pm 2 \times 10^{-3}$
E1	6.8 ± 0.04	$3.4 \times 10^5 \pm 1.6 \times 10^5$	$2.3 \times 10^{-3} \pm 6 \times 10^{-4}$
E2	28 ± 0.25	$3 \times 10^5 \pm 2.4 \times 10^5$	$8.7 \times 10^{-3} \pm 2.1 \times 10^{-3}$
E3	43 ± 1.3	$2.4 \times 10^5 \pm 7.5 \times 10^5$	$1 \times 10^{-2} \pm 5.9 \times 10^{-3}$

(Figure S7, Supporting Information), revealing melting temperatures in the range of 53–59 °C, which is in accordance with stabilities reported for murine scFv constructs.^[41]

Furthermore protein purity was analyzed by size-exclusion chromatography (Figure S8, Supporting Information). For the six generated scFv-Fcs 0.5–15.5% aggregates were determined. Additionally binding kinetics of binders resulting from both immunization campaigns were measured using Bio-Layer Interferometry (BLI). This revealed binding affinities ranging from low single-digit nanomolar to double-digit nanomolar apparent binding constants (Table 1/Figure S9, Supporting Information). Finally, within this study we aimed to demonstrate the applicability of chicken antibodies selected via yeast surface display for biotechnological applications. To this end, the

behavior of the generated hCG binders was analyzed in lateral flow tests (LFT) for detection of small quantities of hCG as it is used in commercially available pregnancy tests (Figure 3A). Two chicken-derived scFv-Fc molecules showing the highest affinity in the BLI analysis were used as capturing antibodies in combination with a commercially available anti-hCG gold conjugate. In both cases, using pregnancy-positive urine as sample, this resulted in clearly visible test lines on the LFT, whereas the application of pregnancy-negative urine led to no visible test band. Further investigations were made to evaluate the limit of detection of the LFTs utilizing the chicken-derived scFvs as capturing antibodies (Figure 3B). This resulted for both binders in a detection limit at concentrations comparable with the LFT performed using the pair of commercially available anti hCG antibodies. To confirm the applicability of the selected EGFR-binding scFv molecules for biotechnological purposes, the selective binding of scFv molecules to EGFR overexpressing cells was analyzed (Figure 3C and D). This resulted for all tested constructs at 100 nM in a highly specific cell-binding to EGFR-positive MDA-MB-468 cells while testing EGFR-negative MCF-7 cells showed no binding.

4. Discussion

Our study confirms the suitability of chickens as immunization hosts for antibody discovery as well as that of chicken-based

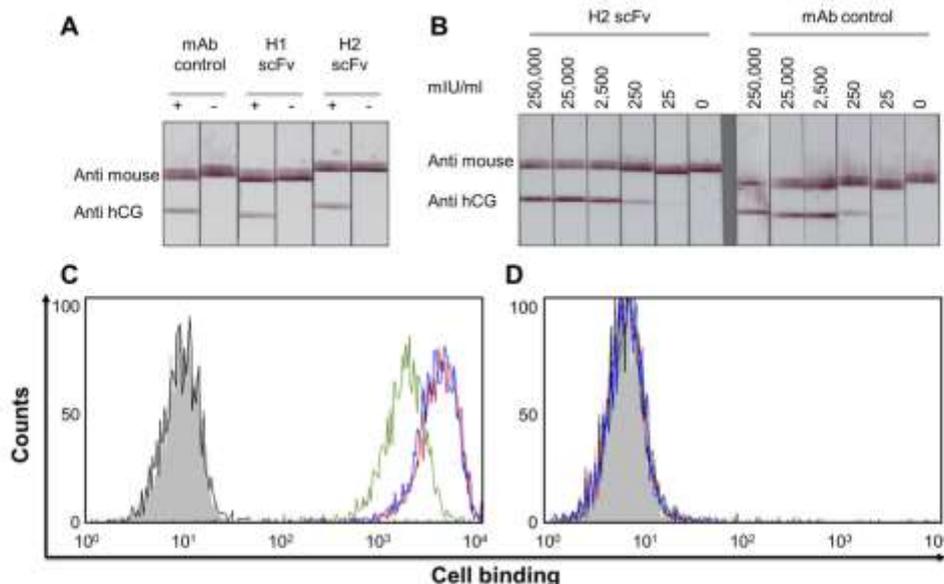

Figure 3. Biotechnological applications of generated scFv-Fc constructs. hCG-binding variants H1 and H2 were used as capturing antibodies in combination with anti-hCG gold conjugate in lateral flow tests using pregnancy-positive (200–400 mIU ml⁻¹) as well as negative urine as sample (A). Limit of detection for scFv-Fc H2 was evaluated using varying concentrations of hCG (B). For EGFR-binding scFv-Fc variants binding to EGFR-positive MDA-MB-468 (C) and EGFR-negative MCF-7 (D) cell lines was determined by flow cytometry. 10⁵ cells were incubated with 100 nM of scFv-Fc variants followed by incubation with an Alexa Fluor 488-conjugated anti-human IgG-antibody. Grey: unstained; black: only secondary antibody; blue: scFv E1; red: scFv E2; green: scFv E3.

antibody formats for generation of antibody fragments displaying high affinity and selectivity. In addition to being low-maintenance animals with relatively low care costs, chickens are evolutionary very distinct to mammals, which presumably resulted in high and rapid immunogenic response to the human target proteins EGFR and hCG. Furthermore, the complete chicken antibody repertoire could be covered to a high degree using two single primer pairs for the heavy and light chains, respectively. This enabled facile yeast library construction, while ensuring high library diversity. Moreover, for the generation of the scFv fragments, the amplified V_{H1} and V_{L1} genes were randomly combined, which on its side increased the library diversity tremendously and could have led to the generation of variants with increased affinities.^[46]

Using FACS, we achieved enrichment of nearly exclusively antigen binding populations in only two screening rounds. Sequence analysis of the isolated binders revealed on one hand clustering of similar CDR3 regions, while on the other hand the clones showed still high sequence diversity. Thus, it is tempting to speculate that extended sequencing of more single clones would lead to identification of even more unique binders. Additionally, the presence of non-canonical cysteines was observed in the analyzed sequences. This is in accordance with the literature^[21] and demonstrates that chicken antibodies are characterized with disulfide bond-constrained CDR3s, presumably as a strategy for additional structural diversification as compensation for the otherwise restricted germline V-gene repertoire.

Heterologous expression of selected scFvs as Fc fusion proteins in a mammalian Expi293FTM system was successful and after purification protein yields of 20–100 mg per liter cell culture were obtained. The melting temperatures of the constructs lies in the expected range of 53–59 °C.^[41] If required, further increase of the thermal stability may be achieved by reformating the scFvs as conventional full-length antibodies.

Ultimately, we demonstrate that in addition to the well-established phage display technology,^[13] also yeast surface display in combination with FACS could be successfully implemented for the generation and selection of chicken-derived scFvs against mammalian target proteins. One advantage of the herein presented screening strategy lies in the online control of the binding properties of the enriched candidates, which also enables epitope binning. This is especially beneficial for applications like sandwich immunoassays (e.g., ELISA and LFT), where a pair of two antibodies, binding different epitopes on the same target protein, is required.^[4] We were able to demonstrate the favorable feature of this system in case of hCG, where a contra-screen with TSH was performed. In this way it was possible to identify selective binders against the beta subunit of hCG. The biotechnological applicability of the generated chicken-derived EGFR and hCG binders was proven in functional tests based on immunofluorescent staining and lateral flow assays, respectively. The selected anti-EGFR scFvs showed selective cellular binding to EGFR-overexpressing MDA MB 468 cells. Furthermore, no unspecific binding of the EGFR binders to MCF-7 cells was observed, indicating sufficient specificity of the generated constructs. At the same time, utilizing the hCG binders in a standard LFT revealed comparable functionality and selectivity compared to antibodies used in commercial pregnancy tests.

In conclusion, we have demonstrated that yeast surface display in combination with FACS represents a suitable platform for facile generation of selective and functional chicken-derived scFv molecules. scFvs represent a very convenient antibody format due to their small size and their ability to be produced in prokaryotic expression systems.^[47] However, compared with Fab fragments, they are less stable and more prone to aggregation^[48,49] and thus generally tend to bind with lower affinities than Fabs.^[50] Nevertheless, our screening strategy at low antigen concentration of 1 nM resulted in high-affinity binders with excellent aggregation properties when formatted as Fc fusion proteins. It will be interesting to see, whether further screening of the enriched population of binders by one or more rounds using more stringent conditions using scFv or Fab yeast libraries would deliver binders with sub-nanomolar affinity, albeit most likely at the cost of clonal diversity.

Abbreviations

Aga1p, a-agglutinin I subunit; Aga2p, a-agglutinin II subunit; BLI, Bio-Layer Interferometry; BSA, bovine serum albumin; EGFR, epidermal growth factor receptor; ELISA, enzyme-linked immunosorbent assay; Fab, antigen-binding fragment; FACS, fluorescence-activated cell sorting; GPI, glycosylphosphatidylinositol; hCG, human chorionic gonadotropin; Ig, immunoglobulin; KB, kinetics buffer; LFT, lateral flow test; mAb, monoclonal antibodies; PBS, phosphate-buffered saline; PCR, polymerase chain reaction; scFv, single chain variable fragment.

8.2 Antibody Display Technologies – Selecting the cream of the crop

Antibody display technologies enable the successful isolation of antigen-specific antibodies with therapeutic potential. The key feature that facilitates the selection of an antibody with prescribed properties is the coupling of the protein variant to its genetic information and is referred to as genotype phenotype coupling. There are several different platform technologies based on prokaryotic organisms as well as strategies employing higher eukaryotes. Among those, phage display is the most established system with more than a dozen of therapeutic antibodies approved for therapy that have been discovered or engineered using this approach. In recent years several other technologies gained a certain level of maturity, most strikingly mammalian display. In this review, we delineate the most important selection systems with respect to antibody generation with an emphasis on recent developments.

27 **Abstract**

28 Antibody display technologies enable the successful isolation of antigen-specific antibodies with
29 therapeutic potential. The key feature that facilitates the selection of an antibody with prescribed
30 properties is the coupling of the protein variant to its genetic information and is referred to as genotype
31 phenotype coupling. There are several different platform technologies based on prokaryotic organisms
32 as well as strategies employing higher eukaryotes. Among those, phage display is the most established
33 system with more than a dozen of therapeutic antibodies approved for therapy that have been
34 discovered or engineered using this approach. In recent years several other technologies gained a
35 certain level of maturity, most strikingly mammalian display. In this review, we delineate the most
36 important selection systems with respect to antibody generation with an emphasis on recent
37 developments.

38

39 **1. Introduction**

40 Monoclonal antibodies (mAbs) have proven to be remarkably versatile therapeutics for disease
41 treatment including cancer and inflammatory disorders ¹⁻³. This is exemplified by the fact that as of
42 November 2019, around 80 mAbs have been granted marketing approval either in the US or the EU
43 and 79 antibody-derived modalities were investigated in late stage clinical trials ⁴. Also, from a
44 commercial perspective, antibody-based therapeutics are tremendously successful. In 2018, the global
45 mAbs market was valued approximately 115 billion US dollars and is expected to grow to about 300
46 billion US dollars until 2025 ⁵. Moreover, the majority of top ten drugs by global sales are antibody

47 (Ab) therapeutics with Humira (Adalimumab) still being the most profitable entity ⁶. As such, antibody-
48 based therapeutics are one of the main drivers of revenues of the pharmaceutical market.
49 Antigen-specific mAbs can be obtained by immunization combined with hybridoma technology, which
50 was pioneered in the 1970s by Köhler and Milstein and still remains state-of-the-art in Ab hit discovery
51 ⁷. Alternatively, Ab display systems such as phage display or yeast surface display enable the isolation
52 of molecules with prescribed properties essentially resulting in several mAb therapeutics approved by
53 healthcare authorities ^{5,8-10}. Herein, the key feature enabling the isolation of a desired candidate relies
54 on the linkage of the protein of interest (POI) (i.e. the phenotype) to its genetic information (i.e. the
55 genotype). Hence, this principle of genotype phenotype coupling allows for 'barcoding' of up to several
56 billion different protein variants of which binders can be selected via high-throughput identification in
57 an iterative process. Several different display technologies are available today, comprising for instance
58 ribosomal display, mammalian display, phage display or yeast surface display, with phage display
59 being the most established one ¹¹. In this review, we describe main Ab display systems without raising
60 the claim of giving a full comprehensive picture. We aim at summarizing core principles of different
61 platform technologies with an emphasis on recent developments and trends.

62

63 **2. Antibody formats utilized for Display**

64 Humans produce five different isotypes of immunoglobulins (Igs) referred to as IgG, IgM, IgA, IgD
65 and IgE. Among those, IgG, which can be further divided into four different subclasses, is the most
66 prevalent isotype in the serum ¹². Importantly, IgG is also the most relevant class in terms of therapeutic
67 applications ¹³. The Y-shaped IgG is a complex heterotetrameric protein composed of two identical
68 heavy chains (HCs) as well as two identical light chains (LCs) with a molecular weight of
69 approximately 150 kDa (**Fig. 1**). Each light chain, either assigned to the κ - or λ -type, forms a
70 heterodimer with a heavy chain and two of those resulting heterodimers, which are linked via disulfide
71 bonds (LC-HC as well as HC-HC), represent the intact Ig. Within the molecule, each light chain is

3

72 generally composed of a *N*-terminal variable domain (VL) as well as a constant domain (either CL κ or
73 CL λ), whereas each of the heavy chains of an IgG1 consists of a *N*-terminal variable domain (VH)
74 followed by three constant regions (CH1-CH3). From a functional perspective, this isotype has two
75 identical fragments responsible for antigen binding (fragment antigen binding, Fab) and the fragment
76 crystallizable (Fc part) that mediates effector functions as well as long serum half-life via binding to
77 several distinct Fc receptors and complement proteins ^{14,15}.

78 Each Fab fragment is a heterodimer consisting of the VH-CH1 region of the heavy chain and the entire
79 light chain (VL-CL κ or λ). Within the Fab region domain, VH and VL harbor the antigen binding site,
80 i.e. the paratope. This paratope is composed of three hypervariable loops of the variable domain of the
81 heavy chain and light chain, respectively. These hypervariable loops are referred to as complementarity
82 determining regions (CDRs) and offer extraordinary variability with respect to loop length as well as
83 amino acid composition (most strikingly in CDR-H3). Overall, those CDRs mediate highly specific
84 antigen binding. Since Abs contain two identical Fab arms, antigen binding is bivalent and
85 monospecific by nature. Simultaneous bivalent binding of two identical targets is enabled by the hinge
86 region, which connects both Fab arms as well as the Fc part and mediates sufficient flexibility ¹⁶. Due
87 to their complex nature, display of full-length IgGs is usually difficult to achieve using prokaryotic
88 display systems or technologies engaging lower eukaryotes (of note, full IgGs can readily be displayed
89 using mammalian systems). Consequently, Ab fragments are typically utilized for those platform
90 technologies. Those include Fab fragments ¹⁷ as well as single chain variable fragments (scFvs) ¹⁸.
91 ScFvs only consist of the VH and the VL domains connected by a flexible linker (**Fig. 1**). In addition
92 to this, camelids and sharks produce heavy chain only Abs, where antigen binding is mediated by a
93 single variable domain ¹⁹⁻²¹. These single domain antibody (sdAb) repertoires can also be efficiently
94 accessed employing genotype phenotype coupling ²²⁻²⁴. Moreover, the display of bispecific entities as
95 well as engineered Ab scaffolds has been described in literature ^{25,26}.

96

97 **3. Sources of Antibody Diversity**

98 Different sources of diversity can be harnessed for the construction of Ab libraries. In principle,
99 libraries can be divided into immune libraries and libraries of universal use. Immune libraries are
100 typically constructed from tissues or blood samples of immunized animals²⁷⁻³¹. With the advent of
101 transgenic animals harboring the (partial) human Ig variable region gene repertoire³²⁻³⁸, fully human
102 Abs can be obtained nowadays by the combination of immunization with an Ab display platform of
103 choice³⁹. Moreover, those libraries can be generated based on humans that either have received
104 vaccination or from patients who have suffered from a disease⁴⁰⁻⁴⁵. These kinds of libraries are heavily
105 biased towards a given target, since the Ab repertoire has already been pre-selected *in vivo*. Hence,
106 they typically contain high-affinity variants. However, their applicability is usually limited to single
107 use only.

108 On the contrary, universal libraries can be considered as 'one-stop-shops' for the isolation of antigen-
109 specific Abs against virtually every target. Accordingly, these types of libraries are of general use.
110 Universal libraries can be sub-divided into naïve, synthetic and semi-synthetic approaches⁴⁶. Naïve
111 libraries make use of rearranged Ig V genes from non-immunized donors and, as consequence, typically
112 access the IgM repertoire^{17,47-49}. One of the hallmarks of such libraries relies on their combinatorial
113 nature, i.e. during library construction heavy and light chains are randomly combined. While much
114 efforts were made recently to keep the natural heavy and light chain pairing for immune libraries^{50,51},
115 this random i.e. unnatural pairing is generally considered to be advantageous in case of universal
116 libraries⁵². Many therapeutic antigens are self-molecules, but during B cell maturation autoreactive
117 Abs expressed on the B cell surface (i.e. B cell receptors) are usually eliminated. Generally, it is
118 considered that owing to the random combinatorial assembly of heavy and light chains, this
119 immunological tolerance can be circumvented (at least partially), enabling the generation of Abs
120 targeting self-antigens. Synthetic strategies are intended to maximize the functionality of libraries, e.g.
121 by focusing on developable scaffolds, by obviating the introduction of sequence liabilities or by precise

122 control of loop length and amino acid composition using state-of-the-art methods of molecular biology
123 ^{46,53-58}. Semi-synthetic approaches typically combine natural and synthetic Ab sequences or sequence
124 parts ⁸. Regarding this, one extravagant examples was described by Hoet and colleagues, who
125 combined light chains from autoimmune patients with the human IGHV3-23 framework harboring
126 autoimmune patient-derived CDR-H3 as well as synthetic CDR-H1 and CDR-H2 regions ⁵⁹. Beyond,
127 libraries can also be constructed for a specific intended purpose, i.e. for humanization of candidates or
128 for affinity maturation ⁶⁰⁻⁶⁴.

129

130 **4. Phage display**

131 The most successfully applied platform technology in the context of Ab discovery is phage display
132 (PD). As of today, 14 marketed therapeutic Abs were identified or engineered using this Nobel prize-
133 awarded approach⁶⁵ (**Table 1**), and a multitude of PD derived molecules are currently investigated in
134 clinical trials ⁸. PD has its origins in 1985, when George P. Smith was able to display and affinity purify
135 short peptides (genetically) fused to the pIII minor coat protein of M13 filamentous phage ⁶⁶. With
136 respect to Ab discovery, it was independently shown by three groups in the early 1990s that PD can be
137 exploited for the *in vitro* selection of Ab fragments: the working groups around McCafferty and
138 Chiswell in Cambridge ⁶⁷, Barbas in La Jolla ⁶⁸ as well as Breitling and Dübel in Heidelberg ⁶⁹. In
139 general, the Ab candidate fused to pIII can be integrated into the phage genome ⁶⁷. However, due to its
140 enhanced flexibility, nowadays, the phagemid system is used much more frequently ⁶⁹. Here,
141 expression of the antibody::pIII fusion is uncoupled from phage replication and phage protein
142 production. For single-stranded DNA replication and packaging into phage particles, a morphogenic
143 signal is added. Assembly of functional phage particles is then facilitated by helper phage providing
144 all crucial components for M13 phage packaging. This also allows for utilization of specialized helper
145 phage, e.g. Hyperphage, enabling multicopy display and consequently avidity-based selections ^{70,71}.
146 Eventually, incorporation of the antibody::pIII fusion into the phage coat results in display on the phage

6

147 surface, while the corresponding genetic material resides within the phage particle (**Fig. 2**). Albeit
148 display of full-length Igs has been described ⁷², usually Ab fragments such as scFvs ¹⁸, Fabs ⁵⁹ or single
149 domain entities ²² are employed for PD, owing to a more robust and reliable processing by the bacterial
150 expression host *Escherichia coli* (*E. coli*). One of the main advantages of PD compared to most other
151 platform technologies described in this review is the ease of library generation comprising huge
152 diversities. In this respect, libraries with more than 10¹¹ clones have been constructed ^{73,74}. Hence,
153 highly specific and high-affinity variants in the low nanomolar to sub-nanomolar range can be readily
154 obtained not only from immune libraries ^{22,30,75}, but also from universal approaches, as elegantly
155 reviewed by Almagro and co-workers ⁴⁶. Ab library generation can be conducted in several ways, for
156 instance by sequential cloning of the light and heavy chain repertoire ⁴⁷, *via* splicing by overlap
157 extension PCR ^{76,77} or utilizing type II restriction enzymes for simultaneous introduction of heavy and
158 light chain diversities ^{22,78}. Once constructed, library candidates with desired characteristics such as
159 affinity, selectivity or stability can be selected in a process referred to as panning (**Fig. 2**), inspired by
160 the process of gold mining. To this end, the library of Ab-displaying phage is incubated with the
161 respective antigen. On the one hand, antigens can be immobilized to a solid surface e.g. to
162 nitrocellulose ⁷⁹, magnetic beads ⁸⁰, column matrixes ⁸¹, polystyrene tubes ⁸² or microtiter plates ^{83,84}
163 with high protein binding capacities. On the other hand, panning can alternatively be performed in
164 solution using biotinylated antigens followed by ‘pull-down’ employing streptavidin-coated beads ⁸⁵.
165 Moreover, selections can be carried out on primary cell lines or utilizing recombinant cells expressing
166 the target of choice, clearly demonstrating the vast flexibility of PD. By applying stringent washing
167 steps, the excess of target-unspecific phages can be removed and subsequently, antigen-bound phage
168 are eluted (e.g. enzymatically ^{22,47} or by pH-shift ^{66,86}) and used for re-infection and re-amplification
169 of *E. coli*. Since phagemid-harboring *E. coli* cells only express the antibody::pIII fusion, helper phage
170 infection is again needed for the production of functional phage particles. This iterative procedure is
171 typically repeated for several rounds in order to highly enrich for antigen specific clones followed by

7

172 soluble mAb production and screening for specific binding either by ELISA ⁸⁴, immunoblot ⁸² or flow
173 cytometry ⁸⁷. The ability to produce soluble Ab fragments simultaneously to the expression of the pIII
174 fusion derives from the presence of an amber stop codon placed in frame between the Ab gene and the
175 pIII gene in combination with the utilization of an amber-suppressor strain of *E. coli*. Afterwards, the
176 genetic information of positive hits is retrieved by sequencing. Moreover, sorting stringencies can be
177 increased by implementing different depletion strategies ^{88,89}. Due to its high versatility, PD has been
178 applied in manifold ways for Ab discovery and engineering. In this respect, this technology commonly
179 is the method of choice for the de novo generation of candidates from universal library approaches and
180 consequently a plethora of universal libraries is known today, as described elsewhere ^{46,47,53,54,58,59,73,90}.
181 Moreover, typical other applications of PD are Ab humanization ^{60,91,92} as well as affinity maturation
182 of Abs. Affinity optimization of library candidates by phage display can be executed in many ways,
183 for instance using different mutagenesis strategies ^{62,93}. Another prominent approach is referred to as
184 light chain shuffling ^{94,95}. Here, the heavy chain of a pre-selected binder (or heavy chains from a panel
185 of binders) is paired with the light chain repertoire of a universal library (e.g. naïve) and re-selected
186 under enhanced stringencies in order to obtain affinity-matured hits ⁹⁶. A very elegant PD strategy
187 relies in guided selection ⁹⁷. Here, usually a rodent Ab is employed as template and each of its variable
188 domains (e.g. the VH domain) is paired with the complementary human antibody variable domain
189 repertoire (e.g. the human VL repertoire), respectively, and selected against the original target.
190 Subsequently, both enriched human VH and VL repertoires are combined and further panned in order
191 to isolate antigen-specific binders. Ultimately, this strategy leads to the identification of human Abs
192 having similar properties as the parental non-human clone. Guided selection has been used in
193 combination with PD for the generation of Adalimumab ⁸. Moreover, PD has proven to be versatile for
194 a more extravagant engineering of 'next-generation' mAb entities such as common light chain
195 bispecifics ⁹⁸, common heavy chain bispecifics (also known as $\kappa\lambda$ -bodies) ⁹⁹ or Abs comprising pH-
196 dependent binding properties ^{100,101}.

197 **5. Yeast surface display**

198 In addition to PD, another platform technology that successfully demonstrated to be suitable for the
199 generation of therapeutic Abs is yeast surface display (YSD). YSD enabled the generation of the PD-1
200 blocking Ab molecule Sintilimab, which has gained marketing approval in China for the treatment of
201 refractory classical Hodgkin's lymphoma (**Table 1**)¹⁰²⁻¹⁰⁴. This technology was pioneered in 1997 by
202 Boder and Wittrup and relies on the genetic fusion of the library candidate to a microbial cell surface
203 protein¹⁰⁵. Albeit several different anchor proteins have been evaluated for displaying proteins on the
204 surface of *Saccharomyces cerevisiae*¹⁰⁶⁻¹⁰⁸, the most commonly and successfully applied system is
205 composed of the α -agglutinin complex subunits Aga1p and Aga2p (**Fig. 3**). Here, the POI can be fused
206 *N*-terminally or *C*-terminally to Aga2p, clearly enabling flexibility with respect to the optimal
207 orientation that might be needed for a particular protein^{105,109}. Typically, the resulting plasmid-encoded
208 fusion protein is produced under the control of the galactose-inducible GAL1/10 promoter system,
209 whereas Aga1p, which is also controlled by a galactose-inducible promoter, is integrated into the yeast
210 genome. Upon expression, Aga2p forms two disulfide bonds with Aga1p¹¹⁰. Hence, covalent tethering
211 of the POI is facilitated on the yeast surface, usually resulting in the display of 10⁴-10⁵ copies of the
212 library candidate¹⁰⁵. Although full-length Ig display has been achieved for YSD¹¹¹⁻¹¹³, Ab fragments,
213 for instance scFvs and Fabs, are most commonly exploited in the context of Ab engineering *via* YSD
214^{105,114,115,115-118}. Moreover, sdAbs^{24,119} as well as scaffold proteins are frequently engineered using this
215 platform approach¹²⁰. YSD libraries can be constructed in manifold ways, e.g. by conventional cloning
216¹²¹, in a homologous recombination-based process referred to as gap repair cloning¹²² or by Golden
217 Gate Cloning involving type II restriction enzymes^{123,124}.

218 One of the main benefits of YSD is its compatibility with fluorescence activated cell sorting (FACS),
219 enabling online and real-time analysis of library candidates and consequently precise control over
220 selection on a quantitative basis¹¹. In this regard, a two-dimensionally sorting strategy can be
221 implemented using fluorescently labeled antigens as well as immunofluorescence staining to gate for

222 clones with structural integrity (i.e. clones without frame shifts or stop codons). This can be
223 accomplished by either employing epitope tags or by using fluorescently labeled detection reagents
224 directed against constant components of the protein to be displayed, such as reagents targeting the
225 constant region of the light chain in the case of Fab display (**Fig. 3**)^{39,105}. Alternatively, reporter
226 systems have been described which couple functional protein display to a fluorescence reporter read-
227 out^{125,126}. This allows for fine discrimination of clones based on binding affinities or kinetics.
228 Moreover, due to the presence of more sophisticated quality control machineries for proper protein
229 folding, it is believed that YSD enables the engineering of more complex molecules compared to
230 technologies involving prokaryotes^{11,127,128}. After library sorting, enriched cell populations are
231 expanded, followed by subsequent FACS-based selection rounds. Finally, the genetic information is
232 obtained by sequencing. Additionally, enriched clones can directly be characterized in terms of binding
233 functionality or affinity *via* flow cytometry without the need for subcloning. In direct comparison to
234 PD, the main bottleneck of YSD is confined library sizes. While libraries in the range of 10^9 clones
235 can be readily constructed for YSD^{123,129,130}, libraries for PD are able to outperform this by several
236 orders of magnitude⁴⁶. Nevertheless, it was shown that YSD also allows for the isolation of antigen-
237 specific Abs from universal libraries^{119,131,132}. Moreover, the daily throughput of FACS is limited to
238 the range of approximately 10^9 cells, which, however, can be increased for huge libraries by a pre-
239 enrichment using magnetic-activated cell sorting. One of the main applications of YSD in Ab
240 engineering is affinity maturation^{105,117,133}. Similar to PD, this can be achieved utilizing different
241 randomization strategies, such as CDR-targeted mutagenesis^{119,134} or light chain shuffling¹²⁹.
242 Additionally, it has been shown that YSD allows for facile isolation of high-affinity candidates after
243 animal immunization^{28,29,39,114}. Related to this, Johnson and colleagues demonstrated that the
244 construction of natively paired Ab libraries (i.e. libraries retaining the original pairing of the heavy and
245 the light chain from a distinct B cell) yield proteins with higher sensitivities and specificities after
246 immunization than libraries with random paired chains⁵⁰. Consequently, sophisticated techniques have

247 been established aiming at the maintenance of this natural heavy and light chain pairing ^{50,51},
248 Additionally, YSD can be employed for mAb humanization. Like PD, YSD has proven to be versatile
249 for the engineering of next-generation Abs such as pH-dependent mAbs ¹³⁵⁻¹³⁹, common chain entities
250 ^{123,140}, anti-idiotypic entities ¹⁴¹ or antigen-binding Fc parts ²⁶. A very elegant approach for the isolation
251 of mAbs exhibiting excellent developability properties originating from YSD libraries has been
252 published by Krauland and colleagues ¹⁴². During Ab selection, the authors implemented a depletion
253 step, i.e. a negative selection by employing a polyspecificity reagent, in order to enrich for clones with
254 significantly reduced polyspecific binding. In another work, published by Lerner and colleagues, it was
255 demonstrated that also complex antigens such as G protein-coupled receptors can be targeted by YSD
256 in a FACS-based biopanning approach ¹⁴³. In addition, yeast display can be utilized to scrutinize PD
257 selection outputs in a high-throughput manner ¹⁴⁴.

258

259 **6. Ribosome display**

260 Besides cellular display technologies or approaches involving filamentous phage, cell-free *in vitro*
261 methods were developed with ribosome display (RD) being the most established cell-free platform
262 technology. Herein, compared to cellular display systems, the number of library-members is not limited
263 by the transformation efficiency of the host. This allows for the generation and screening of larger
264 diversities in the range of 10^{12} - 10^{15} variants ^{145,146}. RD mediates genotype phenotype coupling by
265 fusing the library candidate to its corresponding mRNA, which is reverse-transcribed to DNA after
266 selection, PCR-amplified and sequenced (**Fig. 4**) ¹⁴⁷. Technically, the mRNA lacks the information of
267 the terminal stop codon at the end of the sequence encoding for the POI. During translation, the
268 ribosome is stalled at that position on the mRNA, because release-factors cannot enter the A-position
269 of the ribosome, which further impedes the release of the respective polypeptide chain. This results in
270 the formation of mRNA-ribosome-polypeptide complexes. Similar to PD, selections can be carried out
271 by using antigen coupled magnetic beads or antigen-coating on microtiter plates. The isolation of high

11

272 affinity binders can be promoted by applying stringencies, such as a reduced antigen-concentration and
273 an increased washing intensity during subsequent selection rounds. A limiting factor of RD is the
274 accessibility of functional ribosomes per library reaction, which can reduce the library-size on the
275 protein level ^{145,148}.

276 Historically, Mattheakis and colleagues demonstrated the isolation of peptides binding a mAb with
277 high affinity by using the display on polysomes in 1994 ¹⁴⁹. Hanes and Plückthun described RD in
278 1997 for the first time in the context of Ab selections and were able to 10⁸-fold enrich a complete
279 disulfide containing protein (i.e. an anti-hemagglutinin scFv) out of a mixture with another scFv,
280 specific to β -Lactam ¹⁵⁰. For *in vitro* translation, both groups utilized *E. coli* cell extracts. In the same
281 year, generation of antibody-ribosome-mRNA (ARM) complexes using eukaryotic cell extracts was
282 described. To this end, single chain VH/ κ fragments (i.e. a fusion of VH to a complete κ -light chain)
283 specific to progesterone were selected by application of antigen-coupled magnetic beads enabling a
284 10⁴-10⁵ enrichment in a single cycle ¹⁵¹. In another approach, the yeast transcription factor GCN4 was
285 utilized for the generation of a murine immune library, which was subsequently used for RD selection,
286 enabling the isolation of a scFv binding the antigen with a double digit picomolar affinity ¹⁵². This scFv
287 exhibited a 65-fold higher affinity than its "presumed" progenitor with only one amino acid substitution
288 in CDR-L1. Plückthun and colleagues hypothesized that the incorporation of this mutation occurred
289 during the RD process itself and not during *in vivo* Ab maturation. Therefore, the use of RD for
290 molecule selection may overcome tedious optimization steps, as features like the maturation of Ab
291 affinity might be inherent in the RD process.

292 Today, RD has been extensively studied, especially for Ab affinity maturation ¹⁵³⁻¹⁵⁵. Library
293 candidates from immune and PD repertoires have been affinity optimized with improvements of more
294 than 1000-fold ¹⁵⁶. Moreover, RD has been applied to generate high-affinity Abs from a synthetic
295 library (HuCAL) ¹⁵⁷. Unlike cellular display approaches RD allows the simple incorporation of
296 additional diversity also throughout the screening process, by applying gene-shuffling or error-prone

297 PCR amplification. In this regard, selected scFvs against insulin accumulated mutations introduced by
298 Ab amplification with a low fidelity DNA-polymerase, resulting in 40-fold improved binding affinities
299 compared to their progenitors, originally present in HuCAL ¹⁵⁷.

300 Besides RD, mRNA-display or cDNA-display represent complementary technologies, fusing mRNA
301 to puromycin, which is an analogue of a tyrosyl-tRNA and mimics tyrosine and adenosine with part of
302 its structure. Essentially, the amide bond in the puromycin molecule is not hydrolysable and resulting
303 in a physical linkage between the mRNA and its protein at the end of translation ¹⁵⁸. As mRNA is
304 unstable, a puromycin linker DNA is used as a primer for reverse transcription in cDNA-display,
305 forming mRNA-cDNA hybrids ¹⁵⁹.

306

307 **7. Mammalian surface display**

308 Unlike PD or yeast YSD, where mainly one specific methodology dominates the display field, many
309 different systems of mammalian surface display have been developed in parallel. With the advent of
310 sophisticated tools of gene editing and genetic engineering, e.g. CRISPR/Cas9 or transposon
311 technologies, tremendous progress has been made within recent years. This section aims at briefly
312 giving an overview about some of the main techniques and recent trends.

313 Mammalian Ab display offers some distinct advantages compared to other selection techniques
314 described in this review due to the use of cells not only suitable for screening but also for the production
315 of the desired proteins. The mammalian expression and secretory apparatus is particularly favorable
316 for the production of properly folded full-length Ig molecules with human glycosylation patterns and
317 other post-translational modifications. The vast majority of marketed Ab therapeutics is produced in
318 mammalian cells ^{160,161}. Hence, a mammalian platform technology for Ab selection enables processing
319 of library candidates similar to the final production cell line. Furthermore, this also facilitates a
320 thorough selection for high-level expression besides the binding functionality by FACS. Thereby
321 greater insights into the detailed characteristics of the respective library candidate can be obtained.

13

322 Mammalian cell surface display of Abs is typically enabled by the genetic fusion of the C-terminus of
323 the heavy chain constant region to a transmembrane domain e.g. of the murine H-2Kk protein or the
324 human platelet-derived growth factor (PDGF) receptor (**Fig. 5**)^{162,163}. While transient transfection has
325 traditionally been used for library construction in mammalian cells¹⁶⁴, the field rapidly shifted to stable
326 library generation due to a much more robust genotype phenotype coupling¹⁶³. Since transiently
327 transfected cells generally produce the Ab only for a certain time period, the introduced plasmid DNA
328 must typically be rescued after one round of selection, clearly impeding throughput and convenience
329 in handling^{164,165}. This is in stark contrast to stable library generation, where, in theory, infinite rounds
330 of selection can be carried out without plasmid loss^{163,165-168}.

331 In addition to surface display, simultaneous secretion can be achieved, for instance, by inclusion of
332 LoxP sites flanking the sequence which encodes for the membrane anchoring protein domain, yielding
333 cryptic splice donor sites. The alternatively spliced product lacks the transmembrane domain and is
334 directly secreted into the medium, which enables further biophysical characterization of Abs expressed
335 by selected cells^{162,163}. As example, Waldmeister and colleagues used the supernatants from sorted
336 clones for affinity determination but also checked their suitability as antibody-drug conjugates in a
337 secondary ADC cell killing assay¹⁶⁷. In a recent publication, Aebischer-Gumy and colleagues turned
338 this concept upside-down resulting in a proportion of the secreted protein as displayed molecule on the
339 cell surface by alternative splicing using the chicken cardiac troponin intron 4 between the coding
340 sequence of the HC and the transmembrane domain¹⁶⁹. Due to the small size (0.5 kbs) of the chicken
341 cardiac troponin intron 4, it can easily be used in plasmids for Ab display compared to the natural
342 intron of the Ig gene (5 kbs), which has been used with transposable vectors^{167,169}. The technology
343 called SPLICELECT™ claims that the level of cell surface display can be correlated with expression
344 titers and product quality attributes. In addition, the intron sequence can be modified in a nature either
345 favoring display or mAb secretion, clearly enabling a certain degree of flexibility. Beyond, alternative
346 strategies for simultaneous display and secretion have been described by utilization of, i.e. by a leaky

347 translation termination signal between the HC of the Ab and a transmembrane domain ¹⁷⁰, by non-
348 sense codons ¹⁷¹ or by amber suppression ¹⁷².

349 One of the biggest challenges in mammalian display is the construction of large libraries comparable
350 to those in bacteria or yeast. Depending on the strategy chosen for stable cell library generation,
351 multiple or single copies of Ig genes can be integrated into the genome either randomly or in a site-
352 specifically manner. Standard transfection, viral transduction or transposon technologies for library
353 generation can yield clones with multiple DNA integrations encoding for different Ab genes ¹⁶⁶⁻¹⁶⁸. Of
354 note, polyclonal display negatively impacts genotype phenotype coupling, and consequently the
355 isolation of the genetic information of a favored library candidate. Besides, due to the presence of
356 different Ab chains, mispaired heavy and light chains are displayed and the enrichment of specific
357 clones can be hampered substantially. To obviate this, the DNA utilized for transfection or viral
358 particles can be titrated carefully, thereby enabling an average of one transfected cell displaying only
359 one protein variant¹⁶⁶⁻¹⁶⁸.

360 In general, irrespective of titration in order to obtain pseudo-monoclonal display, large libraries can be
361 generated by random introduction of Ab genes into cells using viral transduction or transposon
362 technology ^{166-168,173}. The Transpo-mAb display platform e.g. applies DNA transposition to generate
363 mammalian cell libraries with a potential complexity of 10^9 by simple transfection ¹⁶⁷. Libraries of
364 more than 10^9 clones have also been generated by B cell transduction with retroviral particles carrying
365 light chain and heavy chain diversities, respectively, as described by Breous-Nystrom in 2014 ¹⁶⁸.
366 However, one of the main downsides of random Ab gene insertion is the variation in the expression
367 level, which strongly depends on the transcriptional activity at the integration site.

368 In recent years, mammalian display made significant advances due to the application of progressive
369 genetic engineering tools, i.e., CRISPR/Cas9 or TALE nucleases. Genetic engineering can be used to
370 efficiently create libraries of up to 10^7 clones with strictly monoclonal display as well as gene insertion
371 at a pre-defined integration site ¹⁶³. In this respect, the group of McCafferty was able to create a

372 functional chain-shuffled library of 1.8×10^6 clones using a population of VH genes pre-selected
373 against PD-L1 combined with a repertoire of light chains. Novel high-affinity IgGs specific for PD-L1
374 could be selected from this mammalian Ab display library ¹⁶³. In a different set-up Cas9-driven
375 homology-directed repair (HDR) has been used to generate site-directed mutagenesis antibody libraries
376 with about 10^5 variants ¹⁷⁴. Herein, variations were introduced utilizing single-stranded
377 oligonucleotides as the donor template at individual complementarity determining regions of a pre-
378 integrated Ab gene in a modified hybridoma cell line, referred to as plug-and-(dis)play hybridomas
379 ^{174,175}. The group was able to increase Cas9-mediated integration efficiency by more than 15-fold in
380 the hybridoma cell line by improving an HDR plasmid donor setup that applies *in situ* linearization ¹⁷⁶.
381 Furthermore, this allowed for the efficient integration of complete VL and VH chain cassette libraries
382 into the genome of the hybridoma cells. Interestingly, in another publication, the group combined
383 mammalian library screening with machine learning. To this end, they trained a neural network by
384 screening and deep-sequencing fractions of rational site-directed mutagenesis libraries based on the
385 therapeutic entity Trastuzumab. By using this approach, antigen-binding could accurately be predicted
386 based on Ab sequences from an *in silico* library of $\sim 10^8$ variants, which was confirmed by the
387 expression and characterization of 30 mAbs ¹⁷⁷. In future, this strategy could guide the rational design
388 of mammalian Ab display libraries and help to overcome the remaining challenge of sampling the huge
389 theoretical sequence space.

390 Another benefit of mammalian cell display relies on the possibility to directly implement somatic
391 hypermutation (SHM) *in vitro*. Naturally, SHM is mediated by the enzyme activation-induced cytidine
392 deaminase (AID) and is an essential process for optimizing Ab affinity ¹⁷⁸. In 2013, Bowers and
393 colleagues have used SHM directed by AID to affinity mature and isolate antibodies ¹⁶². In a first step,
394 cells displaying Abs with a rather low antigen affinity were selected and their functionality was tested.
395 In a second step, those variants were affinity optimized by *in vitro* SHM mediated by AID expression.
396 This procedure enabled the evolution of functional high-affinity binders. In 2020, this technology has

397 been further improved by Luo and colleagues through reengineering of the AID enzyme, optimizing
398 the Ab sequence and the AID gene transfection procedure ¹⁷⁹. Besides selection, affinity maturation
399 and production of antigen-specific Igs, mammalian display also allows to directly transduce reporter
400 cells with an Ab library and, thereby, to directly screen for agonistic or antagonistic molecules as shown
401 by Lerner and colleagues ¹⁷³. In this work, EpoR specific binders were enriched via PD and selected
402 genes were switched afterwards into lentiviruses for the transduction of reporter cells. These reporter
403 cells were infected with one to four different lentiviruses resulting in an expression of the Abs inside
404 the cell as well as a secretion of the molecules. A subsequent phenotypic screening enabled the
405 selection of heterodimeric bispecific agonistic molecules. The same group was able to confirm this
406 concept in another publication by selecting an agonistic Ab specific for the granulocyte colony-
407 stimulating factor receptor (G-CSFR) inducing human CD34+ stem cells to form neural progenitor
408 cells ¹⁸⁰.

409

410 **8. Bacterial display**

411 Bacteria have been utilized for surface display in order to combine fast growth rates as well as easy
412 and cost-efficient handling with real-time multiparameter fluorescence analysis for cell sorting. Similar
413 to mammalian display, a variety of different technologies, each employing unique setups, have been
414 reported of which some will be discussed in the following.

415 Francisco and colleagues, e.g., utilized the translocation properties of the major lipoprotein (lpp) of
416 *E. coli* in combination with the outer membrane protein A (ompA) mediating the anchorage of the
417 antibody on the outer membrane to achieve surface presentation ¹⁸¹. Subsequently, this system was
418 used to affinity mature an anti-digoxin scFv, which resulted in the isolation of a binder with sub-
419 nanomolar affinity ¹⁸². Additional approaches employ alternative bacterial proteins either for display

420 on the outer membrane, such as peptidoglycan associated lipoprotein (PAL)^{183,184}, β -domains of EhaA
421 and intimin¹⁸⁵, or for the display on the inner membrane.

422 In 2004, the anchored periplasmic expression technology (APEX) was published¹⁸⁶. Here, in contrast
423 to the lpp-ompA setup, the Ab fragment is either fused to lipoprotein NlpA (*N*-terminal setup) or to
424 M13 phage gene 3 minor coat protein (g3p) (*C*-terminal setup) and displayed on the inner membrane.

425 Another approach is the MAD-TRAP system, described by Karlsson and colleagues, which utilizes the
426 twin-arginine translocation (tat) pathway to achieve inner membrane display of scFv molecules¹⁸⁷.

427 Due to the location of the displayed Ab fragment, the outer membrane and cell wall need to be
428 permeabilized or removed with EDTA and lysozyme in order to achieve accessibility for antigen and
429 staining reagents.

430 The more sophisticated display of full-length Abs was achieved by Mazor and colleagues expanding
431 the APEX system. To this end, the protein A-derived Ab-binding ZZ-domain was fused downstream of
432 NlpA and displayed on the inner membrane of *E. coli*¹⁸⁸. Additional expression of the light as well as
433 the heavy chains and subsequent secretion into the periplasm allowed for capturing the full-length Igs
434 via the ZZ-domain. In contrast to the display of immobilized Ab fragments, the periplasmic expression
435 with cytometric screening (PECS) technology exploits periplasmic expression of Abs, which are
436 retained by the outer membrane¹⁸⁹. Further, the antibody-antigen complex is detected by antigen-
437 fluorophore conjugates which are limited to around 10 kDa owing to same permeability limitations
438 retaining the Ab in the periplasm. More recently, Lombana and colleagues employed a lpp knock out
439 *E. coli* strain for non-immobilized full-length IgG display¹⁹⁰. Due to the lpp gene deletion and
440 supplementation with EDTA, the loss of outer membrane integrity allowed for antigens and
441 immunostaining agents of up to 100 kDa to enter into the periplasm.

442 Besides surface display employing gram-negative bacteria, several approaches emerged relying on
443 gram-positive bacteria such as *Staphylococcus xylosus*, *Staphylococcus aureus* or *Staphylococcus*
444 *carnosus*. In these approaches, Ab fragments are either anchored by the cell surface attachment regions

445 of protein A (XM domain) directly on the cell wall ^{191,192} or by endogenous sortase mediated attachment
446 to peptidoglycan ¹⁹³. The capabilities of the gram-positive bacterial display method were demonstrated
447 by e.g. Fleetwood and colleagues, who screened a VHH immune library against GFP and isolated
448 several high affinity variants ¹⁹⁴. However, low transformation efficiencies for gram-positive bacteria
449 still seems to limit their broad applicability in Ab discovery. Additionally, non-human-like post-
450 translational modifications are drawbacks still existing for the different bacterial display platforms.

451

452 **9. B cell selection**

453 Albeit not being considered an engineered platform technology *per se*, the most natural kind of
454 genotype phenotype coupling is provided by the B cell itself. Besides displaying an Ab variant on its
455 surface in form of a B cell receptor, the B cell carries the corresponding genetic information inside the
456 cell as mRNA. Hence, it is tempting to directly utilize B cells and their Ig repertoire (e.g. after
457 immunization) for Ab discovery. This also affords the benefit to preserve the natural heavy and light
458 chain pairing of a particular B cell, which is advantageous since random reassembly during library
459 generation may cause a loss of specificity and affinity ⁵⁰ or even evoke self-reactive molecules (which
460 is wanted for universal libraries as discussed above but may be considered as detrimental for immune
461 approaches) ¹⁹⁵. In contrast to hybridoma technology, selecting B cells directly obviates the need for
462 cell fusion with tumor cell lines which is typically a tedious and inefficient procedure and might also
463 result in polyclonal Ab variants ¹⁹⁶. Moreover, with hybridoma one is kind of restricted to certain
464 species, while exploiting B cells for selection enables mining of (in theory) every species imaginable.
465 In general, single B cell Ab selection is a consecutive multi-step process. At first, (antigen-specific)
466 single B cells must be detected within a population of different cells. After detection and isolation, the
467 genetic information encoding for the Ab variable genes have to be obtained by molecular biology
468 techniques, e.g. RT-PCR, and subcloned into adequate expression vectors. Finally, the identified
469 variant can be produced and characterized in more detail. Single cell B cell isolation can either be

19

470 performed in a random fashion, i.e. without selecting for the binding functionality, or in an antigen-
471 selective manner which obviously is the more sophisticated and promising approach for hit discovery.
472 To this end, several different techniques have been described¹⁹⁷ utilizing e.g. antigen-coated magnetic
473 beads^{196,197} or fluorochrome-labeled antigens via multi-parameter FACS²⁰⁰. In this regard, one of the
474 most commonly applied methodologies for the isolation of antigen-specific B cells is fluorescence-
475 activated cell sorting. Here, a multi-parameter labeling strategy can easily be employed. For instance,
476 fluorescently labeled Abs against surface markers of B cells (such as CD19) can be utilized to gate for
477 the specific B cell population within a tissue sample. Application of fluorochrome-labeled antigen
478 further enables the isolation of antigen-positive B cells. In addition to this, the involvement of next
479 generation sequencing (NGS) for high-throughput sequencing of Ig genes in single B cell approaches
480 allows for gathering detailed information about the diversities and dynamics of B lymphocyte
481 populations in individuals^{201,202}.

482 To this date, several human mAbs addressing different diseases have been developed based on single
483 B cell selection, of which several are currently under clinical evaluation²⁰³⁻²⁰⁷.

484 Complementary to B cell selection and other *in vitro* display methodologies described herein, certain
485 hit discovery campaigns demand screening of secreted molecules directly from mAb producing cells.
486 Recent years have seen unparalleled development of microfluidic applications for Ab discovery, both
487 in academic and pharmaceutical research^{208 209 210}. Microfluidics can support native chain paired
488 library generation^{211 212} as well as direct screening of Ig secreting cells such as plasma cells obtained
489 by rodent immunization²¹³ or plasmablasts from human peripheral blood^{214 215}. Abs secreted from
490 single cells are interrogated after compartmentalization in droplets or nanostructures, such as nanopens
491 or nanowells, mostly by fluorescence-based methods allowing real-time and high-throughput sorting.
492 Methodologies range from selection for binding on recombinant target or cells to internalization or
493 functional screening utilizing reporter gene target cells, as exemplified by recent work from Gérard
494 and co-workers²¹³. While broad diversities of neutralizing Abs against infectious diseases such as HIV,

495 Ebola or COVID-19 have been identified from convalescent individuals ^{215 216 217}, microfluidics can
496 also yield tool ²¹⁸ as well as therapeutic molecules targeting cancer or immunological diseases ^{219 220}.
497 Several companies offer customizable microfluidic chips and Ab screening campaigns ^{208,216,221} and
498 stand-alone devices are commercially available ^{218,222}, further driving development and diversification
499 of microfluidic methodologies for therapeutic Ab discovery.

500

501 **10. Conclusion**

502 Display technologies enable the selection and engineering of Abs with therapeutic relevance. The fact
503 that - to the best of our knowledge - 15 mAb-derived entities have been granted marketing approval
504 either by US, European or Chinese healthcare authorities (**Table 1**), of which ten molecules reached
505 market access within the last five years ⁸, is clearly corroborating the major impact those platform
506 technologies have, with respect to drug discovery. Among all therapeutics obtained by Ab display, PD
507 is evidently the most successfully applied approach with 14 therapeutic molecules, either identified or
508 engineered using this technology. Notwithstanding, meanwhile several mAb-derived entities obtained
509 from other display techniques are under clinical investigation, culminating in the approval of Sintilimab
510 in China ^{9,102}. Essentially, each display technology comes with its own benefits and downsides. For
511 instance, YSD allows for a very precise control over selection due to the possibility of FACS-based
512 real-time and on-line analysis of library candidates ¹¹. However, library sizes are appreciably restricted
513 compared to PD or RD ^{46,129,130,145}. In recent years, mammalian display emerged as promising platform
514 technology for Ab engineering. At least, this can be partially explained by the advent of sophisticated
515 genetic engineering tools such as Nobel-prize awarded CRISPR/Cas9 or transposase-based systems
516 allowing for stable generation of libraries with adequate sizes as well as mono-copy insertions at a pre-
517 defined integration site ²²³. In this respect, a plethora of different technologies have been described
518 ^{163,167,169,175,176}. Ultimately, mammalian display aims at ensuring translatable features for a potential
519 therapeutic candidate after reformatting (i.e. biophysical properties or expression yields), since the Ab

21

520 production and processing apparatus of the library host is quite similar to the final production cell line.
521 However, slow growth rates of mammalian cells can obviously be considered as one significant
522 limitation compared to prokaryotic display systems or platform technologies based on lower
523 eukaryotes. Beyond display technologies, microfluidic systems were developed that have proven to
524 support mAb discovery from Ig secreting cells, such as plasmablasts or plasma cells ^{213,215}. In addition
525 to select exclusively for binding, those devices also enable the implementation of functional screenings.
526 As such, microfluidics has the capability to enrich the toolbox for Ab hit discovery. This also holds
527 true for NGS which can be combined with literally every platform technology imaginable ²²⁴⁻²²⁸.
528 Additionally, NGS can be used as platform technology for Ab hit discovery on its own ^{229,230}.
529 Eventually, it will be interesting to see how all these different approaches contribute to the global drug
530 discovery engine within the near future.

1010

1011 **Table 1: Antibodies granted marketing approval discovered or engineered using phage display or yeast surface display.**

	Name	Trade name	Company	Display Technology	Approach	Target	Approval	Indication(s)
1	Adalimumab	Humira	Abbott (Abbvie)	phage display	humanization by guided selections	TNF- α	2002 (USA), 2003 (EU)	rheumatoid arthritis, psoriasis, Morbus Bechterew, Morbus Crohn
2	Ranibizumab	Lucentis	Novartis, Genentech/Roche	phage display	humanization, affinity maturation	VEGF-A	2006 (USA), 2007 (EU)	wet macular degeneration
3	Belimumab (LymphoStat-B)	Benlysta	CAT, human Genome Sciences, GlaxoSmithKline (GSK)	phage display	initial selection	B-lymphocyte stimulator (BLyS, BAFF)	2011 (USA, EU)	systemic lupus erythematosus (SLE)
4	Raxibacumab	ABThrax	human Genome Sciences/CAT, GSK	phage display	initial selection	B. anthracis PA	2012 (USA)	anthrax
5	Ramucirumab	Cyramza	Imclone/Dyax/Lilly	phage display	initial selection	VEGFR2	2014 (USA, EU)	stomach cancer, non-small-cell lung carcinoma (NSCLC)
6	Necitumumab	Potrazza	Eli Lilly	phage display	initial selection	EGFR	2015 (USA, EU)	NSLCC
7	Ixekizumab	Taltz	Eli Lilly	phage display	humanization	IL-17a	2016 (USA, EU)	psoriasis
8	Atezolizumab	Tecentriq	Roche/Genentech	phage display	initial selection	PD-L1, immunomodul.	2016 (USA), 2017 (EU)	bladder cancer
9	Avelumab	Bavencio	Merck KGaA/EMD	phage display	initial selection	PD-L1	2017 (EU, USA)	Merkel-cell carcinoma
10	Guselkumab	Tremfya	Morphosys	phage display	initial selection	IL-23	2017 (EU, USA)	psoriasis
11	Lanadelumab	Taklzyro	Dyax/Shire	phage display	initial selection	Plasma Kalikrein	2018 (USA, EU)	hereditary angioedema
12	Caplacizumab	Cablivi	Ablynx	phage display	initial Nanobody selection	von Willebrandt Faktor	2018 (USA), 2019 (EU)	thrombotic thrombocytopenic purpura
13	Moxetumomab pasudotox	Lumoxiti	Medimmune/AstraZeneca	phage display	murine scFv, affinity maturation	CD22	2018 (USA)	hairy cell leukemia
14	Emapalumab	Gamifant	Novimmune	phage display	initial selection	INF-Gamma	2018 (USA)	hemophagocytic lymphohistiocytosis (HLH)
15	Sintilimab	Tyvyt	Innovent Biologics / Eli Lilly	yeast surface display	initial selection	PD-1	2018 (China)	Hodgkin lymphoma

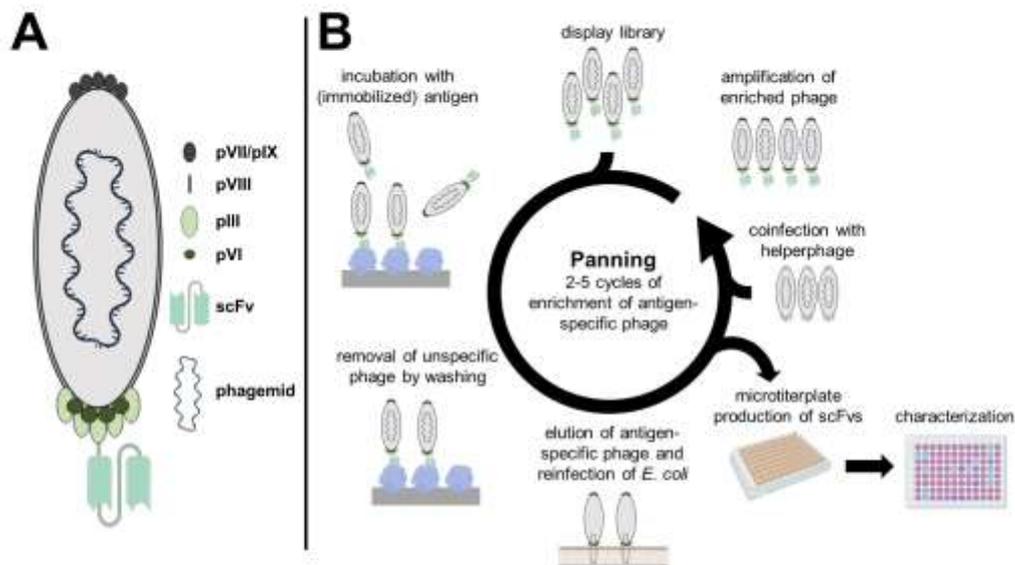

1012

1013 **Figures**

1014

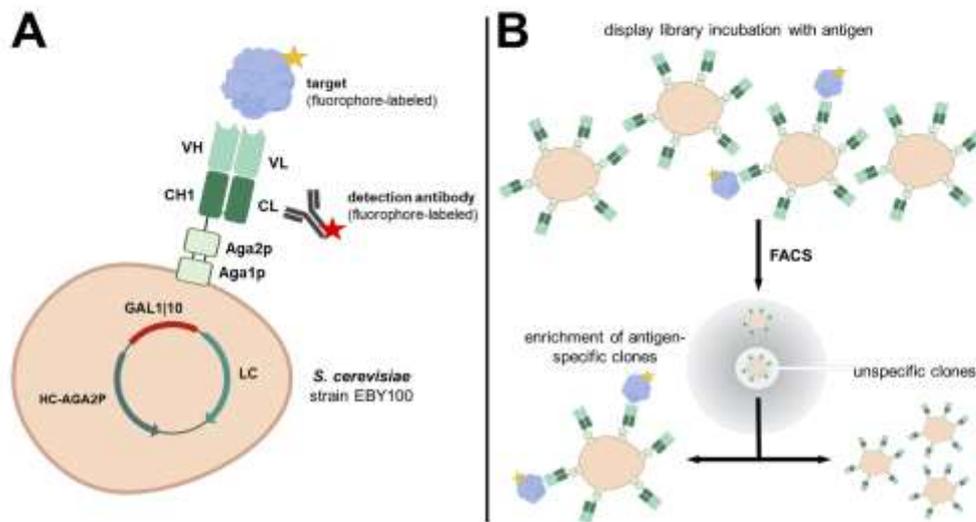

1015 **Fig. 1:** Antibody formats used in different display technologies. (A) Schematic structure of an IgG antibody. VH, variable domain of the heavy
 1016 chain; VL, variable domain of the light chain; CL, constant domain of the light chain; CH1-CH3, constant regions of the heavy chain; H, hinge
 1017 region; Fab, fragment antigen binding; Fc, fragment crystallizable. (B) Model structure of an IgG based on pdb entry: 5dk3²³¹ generated using
 1018 PyMOL v0.99. Variable domains colored in light green, constant regions in dark green and CDRs of one paratope are highlighted in red. (C)
 1019 Schematic depiction of fragments used for display. ScFv, single chain fragment variable; sdAb, single domain antibody. Schemes depicted in
 1020 (A) and (C) generated with biorender (www.biorender.com).

1021

1022 **Fig. 2:** Schematic representation of scFv-displaying phage (A) and phage display procedure (B). Main components of antibody-displaying
 1023 phage are shown (A). pIII, phage protein III; pVI, phage protein VI; pVII, phage protein VII; pVIII, phage protein VIII; pIX, phage protein
 1024 IX. (B) Overview of phage display panning. After library construction, antibody displaying phage are incubated with a particular antigen (here
 1025 shown with surface immobilized antigen). Subsequently, unspecific phage are removed by washing followed by elution of antigen-specific
 1026 phage *via* enzymatic treatment or pH-shift. Afterwards, antigen-enriched phage are exploited for infection of *E. coli* for propagation.
 1027 Coinfection with helperphage enables production and amplification of enriched phage. This procedure is commonly repeated for 2-5 cycles.
 1028 Finally, after reinfection, scFvs can be produced in microtiterplates and utilized for characterization. Components created using biorender
 1029 (www.biorender.com).

1030

1031 **Fig. 3:** Overview of yeast surface display. (A) Schematic illustration of yeast surface display based on *S. cerevisiae* strain EBY100. In this
 1032 representation, expression of the heavy and the light chain for antibody Fab display is enabled by employing a one plasmid system under the
 1033 control of galactose-inducible promoters. Surface display is achieved by genetically fusing the C-terminus of the CH1 domain to Aga2p, which
 1034 upon secretion forms a covalent linkage with Aga1p. Of note, chromosomally integrated Aga1p is not shown. Utilization of fluorophore-
 1035 labeled detection reagents (in this scheme directed against domain CL) as well as fluorescently labeled antigen allows FACS-based gating for
 1036 functional surface expression simultaneous to antigen binding. (B) Process of library selection *via* FACS. After library generation, Fab-
 1037 displaying yeast cells are incubated with the fluorophore-labeled antigen (labeling with detection reagents not shown). Hence, cells displaying
 1038 an antigen-specific antibody fragment can be detected as fluorescence-positive event and sorted. Depending on the type of library, 2-5 rounds
 1039 of selection can be carried out before the genetic information is obtained by sequencing. Scheme generated with biorender
 1040 (www.biorender.com).

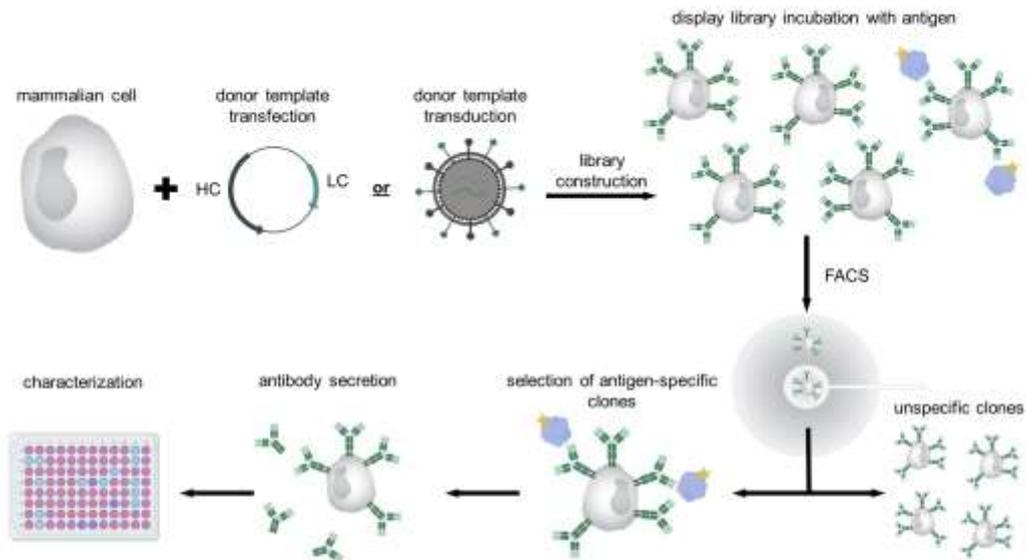

42

1041

1042 **Fig. 4:** Principle of Ribosome display. The amplified DNA library consists of (5' to 3') a promotor, the ribosomal binding site, the gene of
 1043 interest and no stop codon. DNA is transcribed *in vitro* to RNA followed by *in vitro* translation with cell extracts (prokaryotic or eukaryotic).
 1044 At the end of translation, mRNA-ribosome complexes are formed that are incubated with immobilized antigen. After successive washing steps,
 1045 non-binding complexes are removed, and *in situ* RT-PCR followed by PCR-amplification is applied to recover DNA of antigen binding
 1046 variants. This DNA output can either be exploited for post selection characterization or another ribosome display cycle. Figure created with
 1047 biorender (www.biorender.com).
 1048

-43

1049

1050 **Fig. 5:** Schematic representation of mammalian surface display. Antibody libraries can be generated by transfection of mammalian cells with
 1051 plasmids encoding for antibody diversities. In this respect, the use of modern genetic engineering tools ensures mono-copy integrations into a
 1052 predefined site and hence, monoclonal display. Moreover, libraries can also be constructed via transduction or transposase-mediated
 1053 integration. Library sorting by FACS is similar to yeast surface display i.e. via incubation with fluorophore-labeled antigen and detection
 1054 reagents (not shown). In several mammalian systems, owing to simultaneous display and secretion, library cells can be exploited directly for
 1055 antibody production and characterization after several rounds of FACS-based enrichment. Partially generated with Biorender
 1056 (www.biorender.com).

Danksagung

Zuerst möchte ich mich ganz herzlich bei meinem Prüfungskomitee bedanken. Im Speziellen bei Prof. Dr. Harald Kolmar für die Möglichkeit der Promotion in seiner Arbeitsgruppe und der akademischen Betreuung meiner Doktorarbeit. Bei Prof. Dr. Siegfried Neumann für die Übernahme des Koreferats und bei Prof. Dr. Matthias Peipp, sowie Prof. Dr. Johannes Kabisch für ihre Funktion als Fachprüfer.

In diesem Rahmen auch nochmal Danke an Matthias Peipp und Katja Klausz vom Universitätsklinikum Schleswig-Holstein für die hervorragende Projektunterstützung und -zusammenarbeit, die erfreulicherweise schon während dieser Arbeit die ersten Früchte getragen hat.

Dr. Michael Busch danke ich herzlich für die Merck seitige Betreuung im Bereich DiscoPharm bzw. Molecular Pharmacology. Danke für deinen Einsatz, deine Anregungen und Denkanstöße, deine Gesprächsbereitschaft und deine unermüdlich positive Art.

Dr. Stefan Zielonka danke ich herzlich für die Merck seitige Betreuung im Bereich PEAT. Danke für deine schier endlos vielen Ideen für interessante und innovative Projekte, deine mitreißende Art diese Ideen auch zu verkaufen und die Projekte anzugehen. Danke für deine Engagement und teilweise auch die gutgemeinten Schubser in die richtige Richtung.

Dr. Simon Krahe danke ich herzlich für die Unterstützung bei Projekten, die meist doch aufmunternd gemeinten Worte und das offene Ohr für Fragen und Probleme. Danke auch an seine tollkühne Crew im Hefe Labor Filmriss und Dennis für Kost und Logis und sonst auch einfach danke für alles. Dieser Dank geht genauso auch an Rambo, Almuth und Kevin. Danke für die genauso treue Unterstützung beim alltäglichen Merck-Leben.

Dr. Lars Toleikis und Dr. Mirek Jurzak danke ich herzlich für die Möglichkeit dieser Promotion. Ihr habt es mir ermöglicht, eine spannende Arbeit gestalten und Einblicke in die Welt von PEAT und DiscoPharm erhalten zu können.

Vielen Dank auch an die Arbeitsgruppe Kolmar, die immer mit Rat und Tat zu Seite standen und auch an alle Merck Doktoranden und PostDocs: Tim, Janis, Janina, Martina, Jäger, Marie, Desi, Marcel, Lubda, Greg für eure Unterstützung.

Weiterer Dank geht an das Team von Cellular Pharmacology bei Merck, das ich bei euch viele zielführende Versuche machen durfte und sowohl Unterstützung durch Praktisches, als auch in inhaltlicher Art und Weise bekommen habe. Ein großes Danke hier besonders an Jennifer Loehr für die Unterstützung zum Aufstellen des NK Cell Killing Assays.

Danke sagen möchte ich auch bei Sigrid, Stefan, Alex Jenni und Amanda für die analytische Unterstützung dieser Arbeit und an die „Expressionistas“ Pia und Marion für ihre Hilfestellung, sowie bei Marion, Oli und Elli.

Und zu guter Letzt danke ich meiner Familie und meinen Freunden. Meiner Frau Lisa, meinen Sohn Jakob, meiner Tochter Charlotte und meinem Hund Toni für die Bestärkung, Ablenkung und Erdung zu Hause. Ihr steht immer hinter mir und seid immer für mich da! Genauso wie auch meine Eltern Ingrid und Thomas, meine Schwester Judith und meine Oma Hildegard, die mich in meiner Ausbildung seit Beginn an unterstützt haben.

Danke auch an all die anderen, die mich hierbei begleitet und mir zur Seite gestanden haben. Auch wenn ich euch nicht namentlich erwähnt habe, sage ich doch Danke.

Curriculum Vitae

Persönliche Daten

Name	Lukas Pekar (geb. Roth)
Geburtsdatum	28.06.1990
Geburtsort	Flörsheim am Main
Staatsangehörigkeit	deutsch
Familienstand	verheiratet

Ausbildung und wissenschaftlicher Werdegang

2017 – Heute	Technische Universität Darmstadt/Merck KGaA Wissenschaftlicher Mitarbeiter in der Arbeitsgruppe von Prof. Dr. Harald Kolmar am Clemens-Schöpf Institut für Organische und Biochemie an der TU Darmstadt im Rahmen eines Doktorandenverhältnisses in Kooperation mit den Abteilungen „Molecular Pharmacology“ (MolPharm) und „Protein Engineering and Antibody Technologies“ (PEAT) von Merck KGaA
2016 – 2017	Merck KGaA Angestelltenverhältnis als Clinical Engineer in der Abteilung MolPharm der Firma Merck KGaA
2015 – 2016	Merck KGaA Praktikum mit anschließender Masterarbeit in der Abteilung Protein & Cell Sciences Abschluss: Master of Engineering
2013 – 2015	University of Applied Sciences Rhein-Main/ Merck KGaA Masterstudiengang „Bio- und Umweltverfahrenstechnik“ (Abschlussnote 1,1) und wiederholte Werksstudententätigkeiten in der Abteilung MolPharm der Firma Merck KGaA
2013	Merck KGaA Praktikum mit anschließender Bachelorarbeit in der Abteilung MolPharm (mit Auszeichnungen des VDI und ISPE) Abschluss: Bachelor of Engineering
2010 – 2013	University of Applied Sciences Frankfurt Bachelorstudiengang „Bioverfahrenstechnik“ (Abschlussnote 1,3)

Affirmations

Erklärung gemäß Promotionsordnung

Erklärung gemäß §8(1) Promotionsordnung

Hiermit erkläre ich, dass ich die vorgelegte Dissertation selbstständig und nur mit den mir zulässigen Hilfsmitteln angefertigt habe. Die Dissertation wurde in der vorgelegten Form oder einer ähnlichen Fassung zu keinem früheren Zeitpunkt an einer in- oder ausländischen Hochschule eingereicht.

Die schriftliche Version stimmt zudem mit der elektronischen Version überein. Die identische elektronische Version für die Durchführung des Promotionsverfahrens liegt vor.

Außerdem erkläre ich, noch keinen Promotionsversuch unternommen zu haben.

Darmstadt, 26.10.2020

Erklärung gemäß §9 Promotionsordnung

Hiermit versichere ich, dass ich die vorliegende Dissertation selbstständig angefertigt und keine anderen als die angegebenen Quellen und Hilfsmittel verwendet habe. Alle wörtlichen und paraphrasierten Zitate wurden angemessen kenntlich gemacht. Die Dissertation wurde in der vorgelegten oder einer ähnlichen Fassung zu keinem früheren Zeitpunkt an einer in- oder ausländischen Hochschule eingereicht.

Erklärung zum Eigenanteil an den Veröffentlichungen

Im Folgenden ist aufgelistet, mit welchem Anteil ich an den Veröffentlichungen beteiligt war.

Mein Anteil an der folgenden Veröffentlichung beträgt 40 %

[1] Facile generation of antibody heavy and light chain diversities for yeast surface display by Golden Gate Cloning

Mein Anteil an der folgenden Veröffentlichung beträgt 40 %

[2] A One-Step Process for the Construction of Phage Display scFv and VHH Libraries

Mein Anteil an der folgenden Veröffentlichung beträgt 80 %

[3] Biophysical and biochemical characterization of a VHH-based IgG-like bi- and trispecific antibody platform

Mein Anteil an der folgenden Veröffentlichung beträgt 40 %

[4] Affinity maturation of B7-H6 translates into enhanced NK cell-mediated tumor cell lysis and improved proinflammatory cytokine release of bispecific immunoligands via NKp30 engagement (Eingereicht zur Begutachtung am 30. August 2020)

Mein Anteil an der folgenden Veröffentlichung beträgt 35 %

[5] Antibody Display Systems (zur Veröffentlichung angenommen)

Mein Anteil an der folgenden Veröffentlichung beträgt 80 %

[6] Isolation of Antigen-Specific VHH Single-Domain Antibodies by Combining Animal Immunization with Yeast Surface Display.
