

Investigations on mercury sensitivity and molecular determinants of selectivity in two plant aquaporins

Vom Fachbereich Biologie der Technischen Hochschule Darmstadt
zur
Erlangung des akademischen Grades
eines Doctor rerum naturalium
genehmigte
Dissertation von

Muhammad Ayaz

BSc (Hons), MPhil (Botanik)

aus

Multan (Pakistan)

Berichterstatter: Prof. Dr. Ralf Kaldenhoff
Mitberichterstatter: Prof. Dr. Gerhard Thiel

Tag der Einreichung: 05.08.2011
Tag der mündlichen Prüfung: 18.10.2011

Darmstadt 2011

D 17

To the
memories of
my late father

Acknowledgements

I am thankful to my advisor Prof Dr Ralf Kaldenhoff for providing me an opportunity to win the higher ideal of life, his patience, cooperation and continued supervision throughout the research project.

I am grateful to Prof Dr Gerhard Thiel for his willingness to serve as co-supervisor. His productive comments and insights are highly appreciated.

I extend my gratitude towards Prof Dr Adam Bertl (then a senior colleague in the lab) for his unequivocal support and encouragement to get through the difficult times especially during my early days in Darmstadt. I was indeed benefitted from his uncanny ability to turn one's predicament into the moments of delight.

I am thankful to all my lab-mates for providing a pleasant and a friendly work atmosphere. I would like to particularly acknowledge the support rendered by Beate Otto, Dr Matthias Fischer, Dr Norbert Uehlein-Rössner and Nadine Priem. My gratitude is extended to Prof Dr Harald Kolmar and Dr Andreas Christmann for sharing their skills and their support in producing monoclonal antibody.

I will be forever indebted to my parents, sister and brother who enriched my life with love and friendship. I wish to thank my parents for their grooming, their moral support and their affection. The pursuit of a PhD won't have been possible without the financial support of my mother.

Muhammad Ayaz

Structure of the Thesis

This thesis is split into following chapters:

Ch. 1

This chapter introduces aquaporins, their structure and the mechanism of water permeation. Further, it also gives a brief account of various ammonia transporters as well as mechanism of ammonia transport in bacterial AmtB. It also gives detailed review of literature on molecular determinants of selectivity in AQPs.

Ch. 2

This chapter includes description of the results as well as their graphical presentation. Also, the results have been discussed in this chapter. The chapter 2 has been split into 3 sub-chapters.

The sub-chapter 1 involves studies on identification of Hg sensitive site in TaTIP2;2. The effects of some other metals on the pore function have also been investigated. Further, the contrasting mercury sensitivity between ammonia and water permeabilities in TaTIP2;2 has been discussed in detail.

The sub-chapters 2 and 3 involve studies on molecular determinants of selectivity in AQPs, the former sub-chapter deals with the amino acids substitutions outside the selectivity regions whereas the latter one deals with the substitutions inside the said regions. A couple of residues were distinguishable in the sequence alignment comparing water conducting and ammonia conducting AQPs. In sub-chapter 2, these residues were substituted at the corresponding positions between TaTIP2;2 and NtPIP2;1. The outcome of the functional studies as well as the homology models helped discuss the results.

The sub-chapter 3 deals with the corresponding mutations inside the selectivity regions. A remarkable part of this sub-chapter involves studies on chimeric proteins in which a number of structural domains were swapped between TaTIP2;2 and NtPIP2;1.

Ch. 3

This chapter includes material used and the procedures and protocols adopted for manipulating DNA, proteins, bacteria and yeast. The stopped-flow spectroscopy has been introduced in this chapter along with an account of the way permeability coefficients were determined in the present study.

Ch. 4

This chapter concludes the entire research work, briefly highlights significance of the results and gives future recommendations.

Ch. 5 and 6

These chapters include Bibliography and Appendices, respectively.

Table of Contents

1	INTRODUCTION	
1.1	Introduction to Aquaporins	1
1.2	Metal binding in proteins	2
1.2.1.	Mercury sensitivity in AQPs	3
1.3	Structural characteristics of aquaporins	5
1.3.1	Structure of AQP pore	6
1.3.2	Mechanism of water permeation	7
1.3.3	Gas permeation through the tetrameric pore	9
1.4	Ammonia transport through membrane proteins	9
	<i>A. Which ammonia species is transported?</i>	10
	<i>B. Mechanism of ammonia transport</i>	11
1.4.1	Molecular determinants of selectivity in AQPs	12
1.5	Aims of the present study	13
2	RESULTS AND DISCUSSION	
2.1	Studies on metal sensitivity in wheat TIP2;2	14
2.1.1	Comparison of ammonia permeability in various yeast strains	14
2.1.2	Functional studies in Cys mutants	15
2.1.3	Mercury sensitivity in TaTIP2;2	21
2.1.3.1	Attempt to introduce Hg-sensitive site in TaTIP2;2	24
	<i>A. Metal sensitivity requires a Cys residue and this has to be at a particular position</i>	26
2.1.3.2	Reversal of mercury inhibition by β-mercaptoethanol	27
2.1.4	Estimation of cytosolic pH	29
2.1.5	Effects of Cu ²⁺ and Ni ²⁺ preincubation on TIP function	30
2.1.6	General Discussion	33
2.1.7	Conclusions	35
2.2	Molecular determinants of selectivity in AQPs: <i>Investigations outside the selectivity regions</i>	37
2.2.1	Identification of molecular signatures potentially relevant for selectivity	37
2.2.2	Molecular signatures of selectivity in NtPIP2	40
2.2.2.1	Mutational analysis	40
2.2.2.2	Homology modeling and interpretation of the results	43
2.2.3	Molecular signatures of selectivity in TaTIP2;2	47
2.2.3.1	Mutational analysis	47
2.2.3.2	Interpretation of the results	52
2.2.4	General Discussion	53
2.2.5	Conclusions	55

2.3	Molecular determinants of selectivity in AQPs: <i>Investigations on selectivity regions and structural domains</i>	57
2.3.1	Molecular signatures of selectivity in selectivity regions	57
2.3.1.1	Mutational analysis in the ar/R region	57
2.3.1.2	Mutational analysis in the NPA region	60
2.3.1.3	Proton Leakage through SF variants of TaTIP2;2	62
2.3.2	Domain swapping	66
2.3.2.1	Swapping TM helices & connecting loops between TIP and PIP	66
	<i>A. Homology models of a2 and d5 domains of TIP and PIP2</i>	69
2.3.2.2	Swapping C-terminus together with TM6	73
2.3.3	Overview of the section	74

3 MATERIAL AND METHODS

3.1	Procedures and manipulations of DNA	76
3.1.1	Restriction endonuclease Digestion of DNA	76
3.1.2	Agarose gel electrophoresis	76
3.1.3	Isolation / Purification of DNA fragments from agarose gels	76
3.1.4	Determination of nucleic acid concentration	77
3.1.5	Polymerase Chain Reaction (PCR)	77
3.1.6	Gene splicing by overlap extension (gene SOEing)	77
3.1.7	Site-directed Mutagenesis	78
3.1.8	Ligation of DNA fragment	79
3.1.9	Sequencing of DNA fragments	79
3.2	Procedures and manipulations of <i>E. coli</i>	80
3.2.1	<i>E. coli</i> strains used in the study	80
3.2.2	Media for cultivation and transformation of <i>E. coli</i>	80
3.2.3	Preparation of chemically competent <i>E. coli</i> cells	80
3.2.4	Heat-shock transformation of <i>E. coli</i> cells	81
3.2.5	Plasmid isolation from <i>E. coli</i> cells (miniprep)	81
3.3	Procedures and manipulations of yeast	82
3.3.1	<i>Saccharomyces cerevisiae</i> strains used in the study	82
3.3.2	Cultivation of yeast cultures	82
3.3.3	Isolation of plasmid DNA from yeast	82
3.3.4	Biolistic transformation of yeast cells	83
3.3.5	Estimation of cytosolic pH in yeast cells	83
	3.3.5.1 The fluorescent dye “Fluorescein diacetate” (FDA)	84
	3.3.5.2 Plotting a calibration curve	84
	3.3.5.3 Estimation of cytosolic pH	85

3.4	Determinations of permeabilities	85
3.4.1	Stopped Flow Spectrophotometer	85
3.4.2	Determination of ammonia permeability	86
3.4.2.1	Principle	86
3.4.2.2	Loading of yeast cells with Fluorescein diacetate (FDA)	86
3.4.2.3	Experimental Conditions	87
3.4.3	Determination of water permeability	87
3.4.3.1	Principle	87
3.4.3.2	Preparation of yeast protoplasts	88
3.4.3.3	Experimental Conditions	88
3.4.4	Data Analysis	89
3.4.4.1	Calculation of osmotic permeability coefficient (P_f)	89
3.4.4.2	Calculation of ammonia permeability coefficient (P_{NH_3})	90
3.5	Procedures and manipulations of proteins	91
3.5.1	Isolation of membrane proteins from yeast	91
3.5.2	Determination of protein concentration	91
3.5.3	SDS-Polyacrylamide gel electrophoresis (SDS PAGE)	92

1 INTRODUCTION

1.1 Introduction to Aquaporins

Aquaporins are water conducting channels found in animals, plants and microbes. All the aquaporins are water conducting and many of them have been characterized as facilitators of gases like carbon dioxide, ammonia and the larger solutes like glycerol and urea. The physiological roles of aquaporins are continued to be investigated in prokaryotes as well as in eukaryotes and the scientists are much more convinced of their significance as they were at the time of their discovery in 1992 (Preston *et al.*, 1992) that was rewarded by the Nobel Prize to Peter Agre.

Aquaporins belong to the family of major intrinsic proteins (MIPs). Based on the phylogeny, the higher plant AQPs can be classified into the following subgroups: (i) The largest of the four subgroups are PIPs (plasma membrane intrinsic proteins), with 13 isoforms in *Arabidopsis*, (ii) Tonoplast intrinsic proteins (TIPs), (iii) Nodulin 26-like intrinsic proteins (NIPs) which are mainly found in nitrogen-fixing root nodules of legumes, (iv) small basic intrinsic proteins (SIPs) which are localized at the endoplasmic reticulum (Ishikawa *et al.*, 2005). Johanson *et al.* (2001) provided the nomenclature for the current divisions within each of the AQP subgroup mentioned above.

The experimental evidences on specific subcellular localizations are rapidly accumulating, challenging the common AQP classification and demanding its revision (Wudick *et al.*, 2009). Based on function, AQPs were categorized into water-specific aquaporins (AQP1, 2, 4, 5, 6, 8) and aquaglyceroporins (AQP 3, 7, 9, 10) (Jahn *et al.*, 2004). Another family has been informally propounded which is called the super family of AQPs (or superaquaporins). This family is comprised of those AQPs which possess deviations in the NPA motifs, such as AQP11 and AQP12.

Most of the TIP and PIP isoforms are water specific channels, however, some of those may be permeable to other solutes including ammonia, urea and glycerol (Biela *et al.*, 1999, Uehlein *et al.*, 2003, Loque *et al.*, 2005, Liu *et al.*, 2003). TIPs also contribute towards controlling transcellular water transport in roots. The increased vacuolar aquaporin activity may accelerate both cell expansion and cell division by increasing water permeability through the vacuolar membrane (Okubo-Kurihara *et al.*, 2009). Most of the AQPs are localized at the plasma membrane, however, intracellular AQPs also commonly exist (see review of Nozaki *et al.*, 2008). TIP1 (formerly called γ -TIP) of *Arabidopsis* was the first intracellular plant AQP to be found as water permeable (Maurel *et al.*, 1993) and later found to be also ammonia permeable (Loque *et al.*, 2005).

Although the PIP, TIP, NIP and SIP subfamilies are conserved in plants, homology comparisons demonstrate that plant aquaporins have divergent sequence and function. The divergence is found even among the close relatives within a subgroup

for instance members of the TIP sub-family (discussed later in this chapter) and AtPIP2;x (Alexandersson *et al.*, 2005, Sutka *et al.*, 2011).

The expression of each aquaporin gene member is regulated differentially. Some are expressed in a constitutive manner and others are expressed in response to external stimuli, such as water stress (Park *et al.*, 2010). Most PIP transcripts were found to be down-regulated under the influence of water stress (Alexandersson *et al.*, 2005).

1.2 Metal binding in proteins

Almost one-third of the known proteins bind metal ions which serve a variety of roles including regulatory, catalytic and structural (Cousins, 1995). Copper is required by living organisms for cellular processes including signalling of transcription, protein trafficking, oxidative phosphorylation, oxygen transport, electron transfer and respiration (Yruela *et al.*, 2005, Singleton *et al.*, 2008). However, it is highly toxic if its level exceeds the required limits. Nickel and cobalt are essential components of many metalloenzymes (Mulrooney and Hausinger, 2003). Nature has also evolved metal-binding sites which possess no function at all (Banaszak, 2000).

A metal can form a definite or varying complex species with any particular binding site in a protein depending on pH, metal to ligand ratios and metals concentration with variations in the way it would coordinate (La Mendola *et al.*, 2008). The metals like copper and nickel have high affinity for amine groups (Kim *et al.*, 2006). Cu in Plastocyanin is coordinated by one Cys, two His and one weakly bound methionine as in most blue-copper proteins (Ullmann, 2001). Nickel has a high affinity for N of the imidazole ring (Ermler *et al.*, 1998), although it can also bind to negatively charged amino acids (Bar-Or *et al.*, 2001, Jensen *et al.*, 2005). A number of Ni-binding enzymes including Urease in eukaryotes (Dixon *et al.*, 1975), cis-trans isomerase in *E. coli* (Wülfing *et al.*, 1994) and Y3HAO in *Saccharomyces* yeast (Li *et al.*, 2006) have been discovered. Ni also regulates the activity of the water channel AQP3 (Zelenina *et al.*, 2003).

Among all the known functional groups, thiol is the most reactive group. Thiol is the preferential site for binding of toxic metals and hence toxicologically important (Shaw *et al.*, 2004). Mercury has the highest affinity for thiol group and least for phosphate. This characteristic of Hg has been of particular concern in aquaporins (Zelenina *et al.*, 2003). Apart from thiol, imidazole group after losing its proton at a pH of 6-7 also becomes a very good ligand for mercury (Yukutake *et al.*, 2008).

Sulfur exists in a reduced form (-SH) in cysteine and in an oxidized form (-S-S) as the dual molecule cystine. The Hg-S bond distance is 2.4Å (Marking *et al.*, 1998) whereas a disulfide bond is 2.05 Å in length (Hazes and Dijkstra, 1988). The primary sulfur-containing amino acids are cysteine and methionine. Cysteine has unique biological functions, such as being a chelating site for metal ions, or as the active site

of disulfide-reshuffling enzymes (Freedman *et al.*, 1994). The voltage-gated ion channel HCN (Hyperpolarization-activated cation) is blocked by Cd and Mg through coordination with Cys. Probably, multiple Cys residues coordinate with a particular metal ion, however, the involvement of single but different Cys residues is also not ruled out (Rothberg *et al.*, 2002, Vemana *et al.*, 2008). The redox switch in Hsp33 (heat shock protein) is composed of 4 highly conserved cysteines arranged in a C-X-C and C-X-Y-C motif, forming a coordination site for zinc in reduced Hsp33 (Jakob *et al.*, 1999).

1.2.1 Mercury sensitivity in AQPs

Excessive water uptake through AQPs can be life-threatening and the discovery of potent and specific inhibitors of AQPs would open new avenues for manipulating the channel proteins for agricultural and pharmacological applications. Despite their enormous importance, specific AQP inhibitors are still lacking and discovering reversible inhibitors is highly desirable.

The effect of Hg too may be non-specific by targeting various other membrane proteins and it may also hinder cellular metabolism. Hg has a higher affinity for the thiol group and this property of Hg was exploited in the present study for prediction of the pore structure as well as to resolve the contrasting mercury sensitivity between ammonia and water permeabilities as reported by Bertl and Kaldenhoff (2007).

AQP1 was the first aquaporin reported to be blocked by HgCl_2 owing to a Cys residue located at position 189 (Preston *et al.*, 1993). Its side-chain extends into the pore from the extracellular side of the constriction site indicating that inhibition by HgCl_2 is a result of physical blocking of the aqueous pathway (Murata *et al.*, 2000). The mercury-sensitive Cys residue is located 3 residues N-terminal to the second NPA motif. It is now established in case of mammalian AQPs that the presence of a Cys at either a corresponding position to the above-mentioned residue or in the region close to the second NPA motif confers Hg sensitivity (Preston *et al.*, 1993, Raina *et al.*, 1995, Verkman *et al.*, 1995). The AQP7 is insensitive to Hg because of the absence of a Cys at the required position (Ishibashi *et al.*, 1997). In the present study, the above-mentioned position together with nearby residues located inside the pore will be referred to as the “consensus region of metal sensitivity”.

However, there are some exceptional cases including AQP2 (Bai *et al.*, 1996) and AQP4 (Jung *et al.*, 1994a) which could not gain Hg sensitivity even by introducing a Cys at the consensus region. AQP3 is also an interesting case which is sensitive to Hg owing to a residue (Cys11) located in N-terminus (Kuwahara *et al.*, 1997). It seems that the molecular mechanisms behind the mercury effects vary in some AQPs (Yukutake *et al.*, 2008). Hg sensitivity has been demonstrated in AQPs, otherwise insensitive to Hg, by introducing a Cys residue usually in the aforementioned consensus region (Kuwahara *et al.*, 1997). AQP4 was reported to be Hg

insensitive when expressed in oocytes (Hasegawa *et al.*, 1994), but Hg sensitive in the case of liposomes (Yukutake *et al.*, 2008). It was reasoned that in case of liposomes, AQP4 is oriented in a bidirectional manner as against its unidirectional orientation in oocytes. In the former situation, 50% of the reconstituted AQP4 loop D may be exposed to the outside of the proteoliposome. As both the NPA motifs are placed in an antiparallel manner inside the pore, introduction of a Cys residue in loop B (close to the first NPA motif) may take the same charge as Cys189 of AQP1 (Jung *et al.*, 1994b, Shi and Verkman, 1996, Kuang *et al.*, 2001).

An important case is that of AQP6, which is rather activated after treatment of the cells with mercury and the rise in permeability coefficient was almost two-fold compared to the control (Yasui *et al.*, 1999). Similarly, water permeability in AQP1 (from *Anguilla* sp.) was also increased by copper (MacIver *et al.*, 2009).

The reversal of inhibition of the permeability can be achieved in AQPs by using a reducing agent like 2-mercaptoethanol. However, in most cases, the recovery was partial (Yang *et al.*, 2006, Zilli *et al.*, 2009, Jung *et al.*, 1994b) and the lack of complete recovery has been proposed to be the result of several factors (see “Results and Discussion”). With respect to the presence of a separate pore possibly conducting gases, detailed studies on mercury inhibition of ammonia permeability are still awaited. Inhibition of water permeability was either absent (Bertl and Kaldenhoff, 2007) or 10 times less than the inhibition of P_{NH_3} (Niemietz and Tyerman, 2000). These reports support the view of separate pathways for water and gas, i.e. the presence of a putative fifth pore in the aquaporin tetrameric topology.

Apart from Hg, mammalian AQPs (AQP1, 2 and 4) are also inhibited by TEA which is a K^+ ion channel blocker (Müller *et al.*, 2008). It was expected that TEA would inhibit other AQP sub-families, which possess a Tyr at the position homologous to Tyr186 in AQP1. However, introducing a Tyr at the homologous position in otherwise insensitive AQPs didn't show any sensitivity, indicating that Tyr alone doesn't suffice (Brooks *et al.*, 2000, Detmers *et al.*, 2006). Gold and silver have also been reported to inhibit the water specific AQP1 (Niemietz and Tyerman, 2002).

There are two hypotheses prevailing, concerning the inhibitory mechanism of mercury in AQPs: (i) AQPs are inhibited merely because of a steric mechanism inflicted by the presence of mercury atoms in the pore (Fig 1.1) and (ii) Mercury inflicts a conformational change in the AQP because of its interaction with Cys located in the ar/R region (in case of AQP1).

Savage and Stroud (2007), on the basis of structural and functional analyses of the AqpZ mutant, proposed that mercury sterically inhibits AQPs. Based on the Hg-sensitive site Cys189 of AQP1, they constructed the T183C mutant of AqpZ. They superimposed the apo- and Hg-bound structures and found no conformational rearrangement. In a contrasting study, Hg inhibited the water permeability in AQP1 by inducing conformational changes and subsequently collapsing the ar/R region.

However, they did not rule out a simultaneous steric hindrance and/or presence of different mechanisms in different isoforms of AQPs (Hirano *et al.*, 2010).

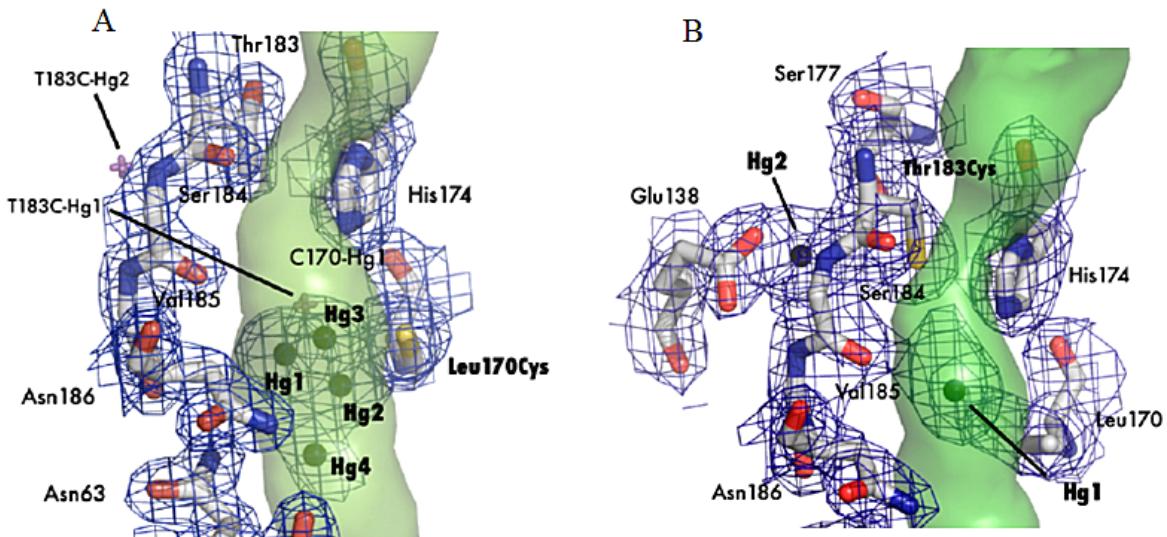

Fig 1.1: Structure of the blocked channel showing steric inhibition by Hg. Amino acids involved with water binding in AQPs are shown as sticks and with $2\text{Fo}-\text{Fc}$ electron density mapped contoured at 1.2σ drawn in blue. Mercury atoms are shown as spheres. (A) Superpositions of Hg atoms from the T183C structure are shown as magenta crosses. This orientation shows that all 3 Hg atoms sterically block the pore. (B) This orientation shows that T183C-Hg1 sterically blocks the pore (green surface) (Adopted from Savage and Stroud, 2007).

1.3 Structural characteristics of aquaporins

Aquaporins exist as a homotetrameric arrangement, where each subunit is an independent water pore. An aquaporin subunit has six membrane spanning domains linked by three extra- and two intracellular loops and both N- and C-terminals are localized in the cytosol (Fujiyoshi *et al.*, 2002). AQP1 tetramers are held together by extensive interactions between the monomers (Murata *et al.*, 2000, Sui *et al.*, 2001). Transmembrane helices 1 and 2 from one monomer form a left-handed coiled-coil interaction with helices 4 and 5 of a neighboring monomer. Helices from neighboring monomers also interact outside the membrane: helix 1 interacts with helix 5 of the adjacent monomer at the extracellular surface and helix 2 interacts with helix 4 of the adjacent monomer at the cytoplasmic surface (Murata *et al.*, 2000, Sui *et al.*, 2001).

1.3.1 Structure of the AQP pore

The AQP pore acts as a two-stage filter. The first and major barrier is the narrowest constriction in the pore known as “ar/R” (aromatic/Arginine) region, which is located towards the extracellular side. The second stage filter in the pore is the NPA (Asn-Pro-Ala) region located at the center of the pore (de Groot and Grubmüller, 2001). The distance between both the selectivity regions is approximately ~10 Å whereas the entire pore length is ~25 Å (Newby *et al.*, 2008).

The two highly conserved NPA motifs are located in loops B and E, which meet in an antiparallel manner and form part of the central pore constriction. Loop B connecting TM helices 2 and 3 folds back to place the first NPA motif at the middle of the membrane. Likewise, the loop E connecting TM helices 5 and 6 folds back to place the second NPA motif opposite to the first one. Both NPA regions are held together by van der Waals interaction between the two Pro residues and also between Pro and Ala residues (belonging to different motifs). Each monomeric channel is composed of two half-membrane spanning repeats, and about half of each repeat is α -helical. The N-termini of the helical repeats meet at the NPA motifs, located near the channel center (Fu *et al.*, 2000, Nollert *et al.*, 2001, de Groot *et al.*, 2003).

The ar/R region (commonly known as selectivity filter; SF) is constituted by 4 amino acids, one constituent is completely conserved Arg (except TIP1 and SIP1) giving the constriction its name. SF of the best known human AQP1 comprises of Phe, His, Cys and Arg. The ar/R region of PIPs, particularly in the case of *Arabidopsis*, contains Phe, His, Thr apart from the Arg. The respective positions will be hereafter referred to as H2, H5, LE1 and LE2. However, TIPs sub-family shows a lot of diversity as compared to PIPs (Wallace and Robert, 2004) (also see Table 1.1). TIPs have 5 different kinds of selectivity filters. The position H2 is always occupied by His in case of TIP1, 2, 3, 4(s). The position H5 is occupied by a smaller hydrophobic residue (Ile, Val, Ala etc) (Bansal and Sankararamakrishnan, 2007). The positions LE1 and LE2 in aquaporins could be important candidates for determining metal sensitive site and the selectivity mechanism, respectively. The former position corresponds to the Hg-sensitive site Cys189 in AQP1 and the latter position has a conserved Arg with interesting exceptions in some TIP isoforms (details will follow in this chapter).

Table 1.1: Aromatic/Arginine signatures that are identical or similar in *Arabidopsis*, rice and maize.

1.3.2 Mechanism of water permeation

The mechanism of water permeation in human AQP1 is described in brief to illustrate the general behavior of the AQP pore. The pore can accommodate only one water molecule at any place in the pore and the molecules are conducted in a single file. At the extracellular side, the hAQP1 pore is wider and the water molecule entering the pore would interact with the A and C loops through Lys36 and Ser123, respectively (de Groot and Grubmüller, 2001). The first major site of interaction with the water molecules is ar/R, which is located close to the extracellular pore mouth and forms the narrowest constriction in the pore (Fig 1.2a). The SF region has a diameter of almost 2.8 Å, which is similar to the size of a water molecule. Water conduction through the SF is facilitated by the presence of hydrophilic moieties however, the rest of the channel is lined by mostly hydrophobic residues exposing the main chain carbonyl oxygens, which serve as hydrogen bonds acceptor for the small-sized solutes (Lee *et al.*, 2005, Sui *et al.*, 2001, Murata *et al.*, 2000). The role of SF in imposing the selectivity barrier in AQPs is discussed elsewhere in this chapter. At this site, a water molecule is rotated at 180° under the influence of electrostatic forces imposed by the short helices HB and HE (de Groot and Grubmüller, 2001). The next site for a major interaction of a water molecule is the NPA region.

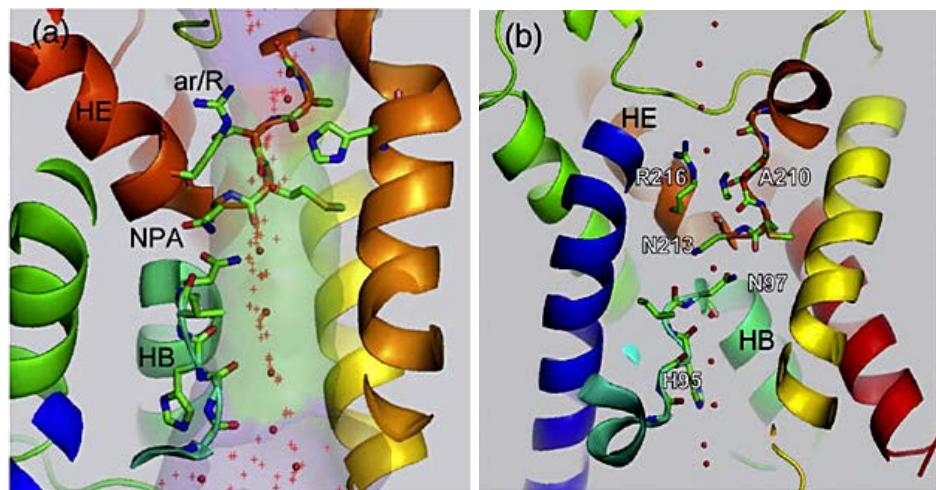

Fig 1.2: Pore view of the AQP4 channel. (a) A side view showing pore diameter presented as a transparent surface. The positions of water molecules seen in other AQP structures available to date are shown as red crosses. The narrowest ar/R region is shaded as red (b) Residues interacting with water molecules (red spheres) in the pore are shown as ball-and-stick models. Adopted from Tani *et al.* (2009).

The Asn residues belonging to both NPA motifs are juxtaposed (Fig 1.2b) and serve in the hydrogen bonding with water molecules (de Groot *et al.*, 2001). Two different modes of coordination between water and the two Asn residues of both NPA motifs have been demonstrated. In bacterial AqpZ and *E. coli* aquaglyceroporin GlpF, a single water molecule inside the pore which is positioned between the NPA motifs, receives hydrogen bonds from both the Asn residues of the motifs (Savage *et al.*, 2003, Tajkhorshid *et al.*, 2002). On the contrary, in AQP4, water is not positioned between the motifs. Also a given water molecule would interact with Asn of only one NPA motif (Ho *et al.*, 2009).

Water molecules keep on moving down the pore interacting with carbonyl groups of the pore-lining residues (Cys189, Gly190 and Ile191 in case of AQP1) (de Groot and Grubmüller, 2001).

The pore widens again toward the intracellular side (Fig 1.2b). After leaving the selectivity regions, water molecules interact just weakly with the narrow constriction formed by Gly72, Ala73 and His74 located in loop B (de Groot and Grubmüller, 2001, de Groot *et al.*, 2003). After interaction with the backbone carbonyl groups of this constriction, water is ready to exit from the pore. Water molecules are escorted out of the pore by a mechanism comprising of His76 and Val155. Interestingly, His76 often kept the pore blocked and was proposed to control the water flow (Sui *et al.*, 2001, Smolin *et al.*, 2008). AQP0 also has a similar phenyl barrier, both at the extracellular (owing to Tyr23) and the cytoplasmic side (owing to Tyr149); both residues are capable of occluding the pore, though by different mechanisms (Jensen *et al.*, 2008).

An important feature of the AQPs pore is preventing the proton conductance. Two mechanisms for exclusion of protons from the pore have been demonstrated: (i) interruption of the hydrogen-bond network for which the short pore helices HB and HE are crucially important (Tani *et al.*, 2009, de Groot and Grubmüller, 2005) (ii) the presence of a strong energy barrier inside the pore. The major barrier, while comparing both the selectivity regions, originates from the ar/R region (Li *et al.*, 2011, Wu *et al.*, 2009). One of the amino acids constituting the ar/R region is a highly conserved Arg. The positive electrostatic potential prevailing in this narrow constriction when shifted towards neutral or even negative would result into leakage of protons through the pore (Beitz *et al.*, 2006, Oliva *et al.*, 2010, Chen *et al.*, 2007). Apart from the Arg, His and the positive dipoles of the short helices HB and HE also impose a strong energy barrier to prevent the conduction of protons (de Groot *et al.*, 2003, see review of Agre *et al.*, 2002).

1.3.3 Gas permeation through the tetrameric pore

AQPs are not only water conducting channels, but have also been demonstrated to facilitate solutes including gases like CO₂ (Prasad *et al.*, 1998, Uehlein *et al.*, 2003) and NH₃ (Jahn *et al.*, 2004, Loque *et al.*, 2005). It is however, still a matter of debate if the gases permeate through the water pore or through the central pore of the tetramer.

The MD simulations revealed full permeation events through the central pore during which both CO₂ and O₂ were observed inside the central pore (Yu *et al.*, 2006, Wang *et al.*, 2007). The water pore was less permeable to gases than the central pore because of the higher energy cost required to replace the interacting water with the protein. Although the conditions are favorable to more hydrophobic O₂, the water pore may conduct CO₂ more efficiently.

Two hydrophobic residues in AQP4 (Leu66 and Leu191) form the outermost gates that restrict the water to enter the central pore (Wang and Tajhorshid, 2010). A similar gating mechanism was also observed in AQP1 (Yu *et al.*, 2006).

1.4 Ammonia transport through membrane proteins

Ammonia is an important nutrient which is taken by living organisms from their surroundings as a source of nitrogen for amino acid synthesis. Higher levels of ammonia are toxic and are to be lowered down at the expense of significant energy. It is present in all compartments of the cell, although its concentration varies depending on a number of factors including ammonia concentration in the neighbouring compartment, changes in electrical potential and pH (Perez-Garcia, 2011, Wright *et al.*, 1995, Miller *et al.*, 2001).

Plants have evolved separate, high affinity transport systems for NH_4^+ and K^+ which may be classified into 2 categories: (i) The low-affinity transport system (LATS) appears to be constitutively expressed and discriminates less well between K^+ and NH_4^+ . (ii) The high-affinity transport system (HATS) is regulated by the nitrogen status of plants; the depletion of nitrogen will lead to an increase in the activity of HATS (Howitt and Udvardi, 2000).

Ammonia exists as two molecular forms NH_3 and NH_4^+ in aqueous solutions. At physiological pH, >98% of total ammonia is present as NH_4^+ (Woeber *et al.*, 1963). The permeability of NH_4^+ is 175 times lower than that of NH_3 . However, the concentration of NH_4^+ available is higher by a factor of 110 because at a neutral pH and a total concentration of 100 mM, only 0.90 mM will be in the form of NH_3 (Abdoun *et al.*, 2005). The manipulation of both factors suggests that for every single millimole passing through the membrane, more than 60% of the total ammonia will be conducted as NH_3 . The Henderson-Hasselbalch equation can be used for determining the ratio between both forms of ammonia at any particular pH. In the present study, the term "ammonia" will be used to refer to both the ammonia species, i.e. NH_3 and NH_4^+ .

The membrane ammonia transporters comprise a family in which ammonium transporter in plants (Amt) (Ninnemann *et al.*, 1994), methylammonium permease (MEP) in yeast (Marini *et al.*, 1994) and the homologues of AMTs in animals that is Rhesus (Rh) (Marini *et al.*, 2000, Liu *et al.*, 2000) are collectively termed as Amt/MEP/Rh.

Although, aquaporins have been widely characterized for their water function, many of these are expected to be ammonia conducting. The molar volume of ammonia ($24.9 \text{ cm}^3/\text{mol}$) is not much higher than that of water ($18 \text{ cm}^3/\text{mol}$). Also, the AQPs are already known to conduct another gas CO_2 (Prasad *et al.*, 1998, Uehlein *et al.*, 2003).

Ammonia-permeable aquaporins are found among those which exclude solutes larger than water (Zeuthen *et al.*, 2006). AQP1 was the first aquaporin reported to be ammonia permeable (Nakhoul *et al.*, 2001). Since then several AQPs have been characterized for their ammonia function which include mammalian AQP8 (Holm *et al.*, 2005, Yang *et al.*, 2006) and plant TIP2;1 (Jahn *et al.*, 2004) among the aquaporins, and mammalian AQP3, 9 among the aquaglyceroporins (Holm *et al.*, 2005).

A. Which ammonia species is transported?

Whether ammonia is transported through the channels in electroneutral (NH_3) or electrogenic (NH_4^+) form is not yet fully understood. In fact, several modes of ammonia transport have been suggested which support electroneutral NH_3 transport,

NH_4^+ /H⁺ antiport, NH₃/H⁺ symport, or NH₄⁺ transport (see review by Søgaard *et al.*, 2009).

The plant Amt proteins studied to date transport charged species i.e. NH₄⁺ (Ludewig *et al.*, 2002, 2003, Mayer *et al.*, 2006). In a similar report, Sohlenkamp *et al.* (2002) changed the pH in the external medium between 5.5 and 8.0 and observed no effect on Km of the ammonium, implying that it is NH₄⁺ and not NH₃ which is being transported through AMT1;1. The crystal structures of bacterial AmtB suggested that the species bound may be NH₄⁺ but the one transported is probably NH₃ (Zheng *et al.*, 2004, Khademi *et al.*, 2004). The fate of dissociated H⁺ was however not determined.

Sequence alignments of the members from MEP and Rh transporters reveal that the pore lining residues are highly conserved, indicating that the entire family conducts uncharged NH₃ (Winkler, 2006). AQPs probably prefer ammonia to permeate as electroneutral species as observed in case of AQP8 (Saparov *et al.*, 2007).

B. Mechanism of ammonia transport:

Crystal structures (Gruswitz *et al.*, 2010, Khademi *et al.*, 2004, Zheng *et al.*, 2004) and MD simulations (Akgun and Khademi, 2011, Yang *et al.*, 2007, Lamoureux *et al.*, 2010, Nygaard *et al.*, 2006) data have demonstrated the mechanism of ammonia transport in bacterial AmtB (Fig 1.3) and the human RhCG. The channel lies between the outer (periplasmic) and the inner (cytoplasmic) vestibules. Ammonia transport involves a periplasmic vestibule, where it is recruited as well as deprotonated because of the reason that the channel would allow only the electroneutral form NH₃. The channel must lower the pK_a of ammonia to ensure that it retains its neutral form throughout the pore length.

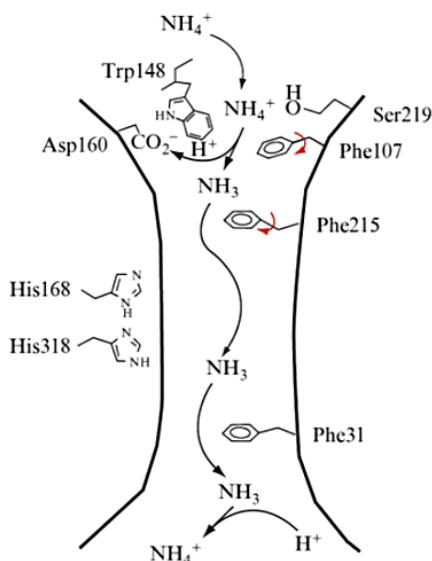

Fig 1.3: Illustration of the NH₄⁺/NH₃ transport mechanism through the *E. coli* ammonia transporter AmtB (Adopted from Khademi *et al.*, 2004).

This periplasmic vestibule is rich in aromatic rings and can bind NH_4^+ through cation- π interactions. It is comprised of Phe103, Phe107, Trp148, Phe215 and Ser219. The channel pathway is controlled by the aromatic rings of two highly conserved residues, Phe107 and Phe215, which are located between the periplasmic vestibule and the lumen. The Phe gate is commonly present in AmtB and the human Rhesus channel. The channel lumen is 20Å in length and is too hydrophobic to transport water (Khademi and Stroud, 2006). Some reports however demonstrated the presence of water molecules inside the pore lumen (Nygaard *et al.*, 2006, Lamoureux *et al.*, 2007). Ammonia is reprotominated at the cytoplasmic site again to form NH_4^+ and is ready to exit.

1.4.1 Molecular determinants of selectivity in AQPs

Both size and hydrophobicity in the ar/R region determine ammonia selectivity. Although the larger solutes like glycerol and urea are restricted sterically, even smaller solutes like H_2O , CO_2 and O_2 may be restricted by higher hydrophobicity in AQP pore (Hub and de Groot, 2008, Wu *et al.*, 2009, Savage *et al.*, 2010). The amino acid composition and their arrangement also don't suffice for selective permeability. An interesting example is Glpf (an aquaglyceroporin) which has a lower water conductance than the water specific pores. The SF of Glpf and the PfAQP (aquaporin of protozoa) are identical but the water permeability of the former AQP is lower (Hub and de Groot, 2008).

The ammonia permeability in AQP8 and TIP2;1 requires that a histidine directly flanks the conserved Arg at the LE1 position of the SF (Zeuthen *et al.*, 2006). If an AQP1 mutant is generated in which the His at position 180 is substituted by Ala, the water specific AQP1 becomes ammonia permeable (Beitz *et al.*, 2006).

Litman *et al.* (2009) compared the variations in the selectivity regions of the predominantly water conducting pores against the ammonia conducting ones (see a logoplot in Appendix I.1). At position H5, water specific AQPs (AQP1, 2, 4, 5, 6) have a His residue, aquaporins permeable to water, glycerol, and ammonia (AQP3, 7, 9, 10) have mostly got a smaller residue, Gly, ammonia- and water permeable AQP8 has an Ile. In case of the ammonia permeable TaTIP2.1, replacing Ile by a His and the Gly at LE1 position by Cys (mimicking the SF composition of AQP1) abolished the ammonia transport function whereas the P_f remained unaffected (Jahn *et al.*, 2004). Focusing the same positions, water specific AQP1 was converted into a ammonia channel (Beitz *et al.*, 2006).

The determinants of selectivity in AQPs are extended beyond the SF region (Liu *et al.*, 2005a, Savage *et al.*, 2010). The AtPIP2 mutants mimicking the ar/R region of AtTIP1, 2 and 4 did not (or minimally) conduct urea, although native TIP1, TIP2 and TIP4 homologs are known to transport this solute. This implied that TIP-like SF

doesn't suffice to induce NH₃ permeability in PIP2. TIP1 channels have a unique ar/R filter, in which the highly conserved Arg is replaced by Val (Table 1.1), this variation however is not critical for ammonia/urea transport (Dynowski *et al.*, 2008).

1.5 Aims of the present study

The present study was aimed at achieving the following objectives:

1. Investigating the already reported contrasting effect of mercury to inhibit water/ammonia permeability in TaTIP2;2 with particular reference to the putative tetrameric pore. Also, it was aimed to determine the mercury-sensitive site by sequentially substituting the native Cys residues.
2. Determination of molecular signatures taking part in ammonia/water selectivity in TaTIP2;2 (ammonia/water channel) and NtPIP2;1 (water specific channel):
 - (i) Functional studies on corresponding point mutations outside the selectivity regions; mutations were suggested by the sequence comparison.
 - (ii) Studies on mutations of corresponding residues in the selectivity regions. The functional studies were also extended to involve the exchange of certain loops and TM helices.

2 RESULTS & DISCUSSION

2.1 Studies on metal sensitivity in wheat TIP2;2

The TaTIP2;2 investigated in the present study is known to be permeable to both water and ammonia. In an earlier report, the ammonia transport was significantly inhibited by HgCl_2 however; the water transport was proved to be insensitive (Bertl and Kaldenhoff, 2007). This difference of sensitivities led me to postulate that water and ammonia transport follows different pathways in TaTIP2;2. The present study was conducted to determine which of the native Cys residue (if at all) is involved in coordination with mercury and subsequent decrease in ammonia permeability. Apart from mercury, other heavy metals like copper and nickel were also employed in this study to determine their effect on water and ammonia transport function of wheat TIP.

2.1.1 Comparison of ammonia permeability in various yeast strains

The present study involved investigation of ammonia and water transport function in a number of variants of the wheat TIP2;2. Incidentally, this aquaporin was contained by the SY1 strain of *Saccharomyces cerevisiae*, which is not perfect for the studies on ammonia transport function as it contains endogenous ammonia/ammonium transporters. Some preliminary experiments, however, revealed that SY1 and a yeast strain (31019b) which has all three putative ammonium transporters MEP1, MEP2, and MEP3 deleted were both nonfunctional for ammonia transport. Despite these results, the strain 31019b was chosen for the entire studies.

Owing to the above-mentioned outcome, it was decided to investigate various yeast strains for their ammonia transport function under our experimental conditions. Altogether, three strains, i.e. SY1 (Nakamoto *et al.*, 1991), BJ5458 (Suga and Maeshima, 2004) and 31019b (Marini *et al.*, 1997) were investigated. All three strains showed a rather low background ammonia permeability; a quite surprising outcome in case of SY1 and BJ5458 strains, which contain the afore-mentioned ammonia transporters. Raw kinetics are presented in Fig 2.1.1. Currently, the only available explanation is that the Mep transporters possess a high affinity for ammonia and are saturated at very low ammonia concentrations (in the μM range) (Loque and WIREN, 2004). In the present study, ammonia concentration used in the outer solution was 25mM which is several orders of magnitude higher. The initial phase of ammonia conductance is fastest but is very brief hence it remains (at least) partially undetected by the photomultiplier. However, this outcome was not further investigated as it was beyond the scope of the present study.

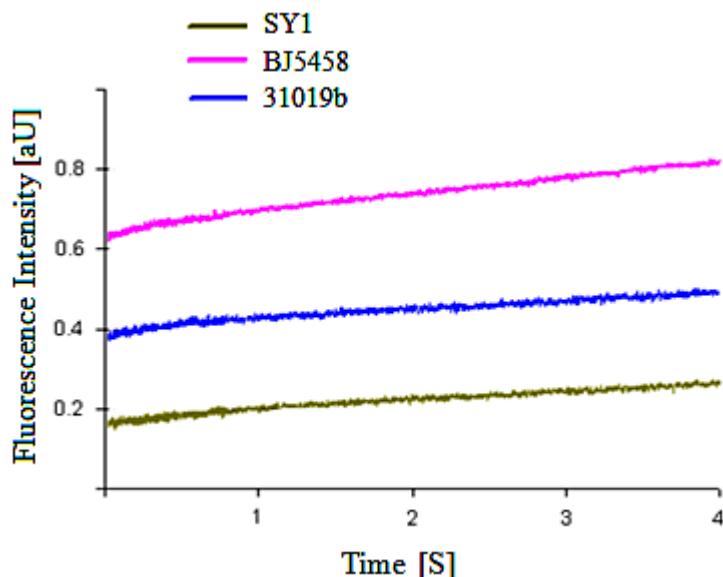

Fig 2.1.1: Ammonia permeability in various strains of *Saccharomyces* is presented as raw kinetics (without normalizing). The time courses represent changes in fluorescence intensity due to change in pH after subjecting the yeast cells to an outer solution containing 25mM NH₄Cl. Each time course is the average of 20-40 kinetics obtained from 3 individual experiments. The total number of traces acquired for each of the constructs was at least 50. Note: (i) the strain 31019b is devoid of any endogenous ammonia transporters (see the text for details on given strains), (ii) the time courses of ammonia permeability in non-transfected yeast as well as the yeast cells containing an empty vector were similar.

2.1.2 Functional studies in Cys mutants

There are three native Cys residues in TaTIP2;2 at positions 63, 123 and 237. Cys63 is located in transmembrane helix 2, Cys123 in TM 3 and Cys237 in the C-terminus (Fig 2.1.2). Cys123 has been presumed to be of particular significance being a possible “analog” to the well-characterized mercury-sensitive Cys residues located in loop E of a number of orthodox AQP (for instance Cys189 in AQP1) (Preston *et al.*, 1993). In contrast, Cys237 was considered to be least significant as there is no report available to-date concerning the involvement of any C-terminal residue in heavy metals sensitivity of AQPs.

Therefore the latter Cys was omitted and the other two native Cys residues were mutated to alanine resulting in the C63A and C123A mutants. Further, a double mutant (C63A/C123A) was also generated substituting both the native Cys residues. To analyse the function of these mutants in comparison to the wild type wheat TIP, the constructs were transferred into the heterologous yeast expression system. Water permeability coefficients (P_f) of yeast protoplasts were determined after hypoosmotic shock prior to or after HgCl₂ pre-treatment. The time courses of wild type and various mutants of TaTIP2;2 are presented in Fig 2.1.2 The data revealed that P_f values for wild type TaTIP2;2 and the mutant C63A were not significantly different.

However, the rest of the mutants including C123A and the double mutant C63/123A exhibited significantly higher coefficients of osmotic permeability (Fig 2.1.4A). See Appendix 1A for detailed P_f values comparison. The increased P_f due to substitution of Cys123 implies a structural and/or functional role of Cys at this position.

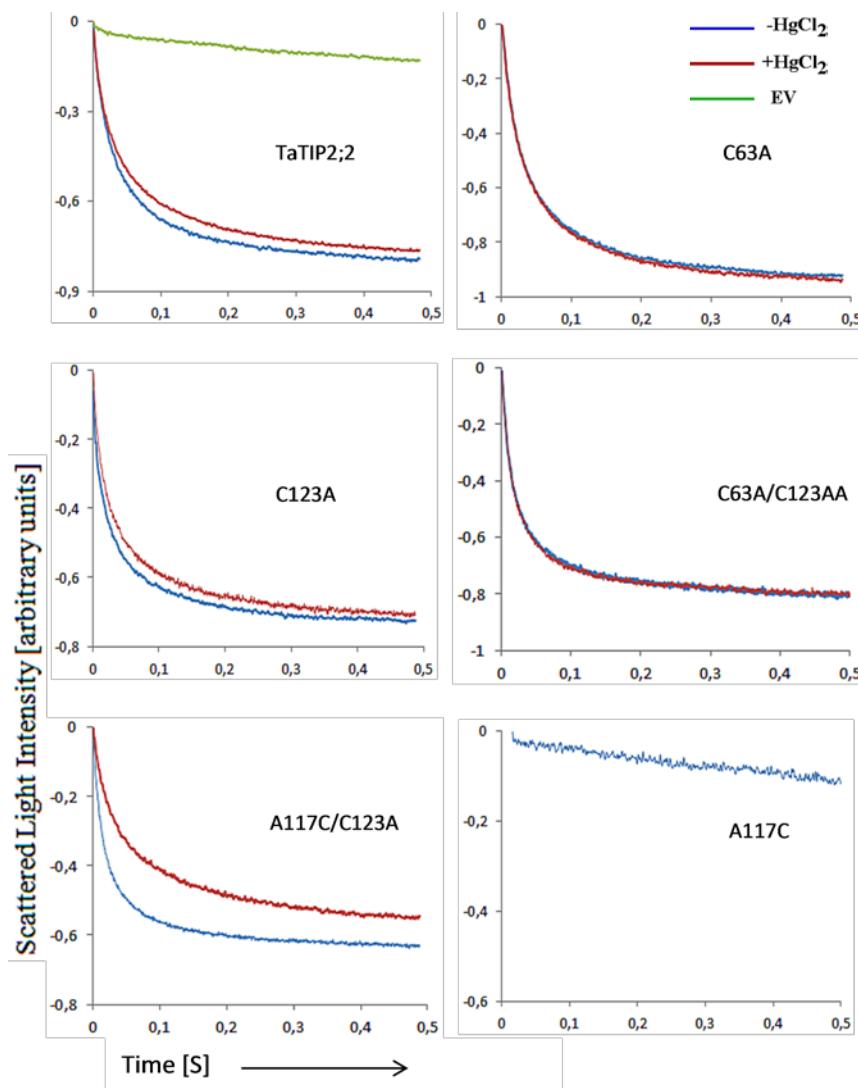

Fig 2.1.2: Water permeability and its inhibition by mercury in protoplasts of *Saccharomyces cerevisiae* yeast cells. The figure contains time courses of changes in scattered light intensity in TaTIP2;2 and its mutants after subjecting the yeast cells to a hypoosmotic shock of 300 mosmol with and without preincubation with 1mM HgCl₂. All the time courses are presented after normalization, however the panel for A117C mutant shows a raw time course (without normalizing) due to the reason that normalization elevates the initial brief but faster component by several orders of magnitude. Each time course is the average of 20-40 traces obtained from 3 individual experiments. The total number of traces acquired for each of the constructs was at least 50. Note different scales along the y-axis. Also note that the followings are described in detail under separate captions in this chapter: (i) the investigation on Hg-sensitivity in TIP is described in detail under the caption 2.1.3, (ii) the Ala-to-Cys mutants (single and double) involve introduction of a Hg-sensitive site into TIP and are described in detail under caption 2.1.3.1.

The afore-mentioned Cys-to-Ala mutants were also subjected to stopped-flow spectroscopy to study ammonia permeation. The time courses of wild type TIP and its various mutants are presented in Fig 2.1.3. All the single and double mutants (except C63A) were faster in P_{NH_3} (Fig 2.1.4B) compared to the wild type TIP. The rise of P_{NH_3} in case of the single mutant Cys123 as well as both the double mutants (C63/123A, A117C/C123A) was approx. 30% of the P_{NH_3} value of wild type TIP. The mutant C63A was just slightly slower than the wild type (See Appendix 1B for detailed comparison of P_{NH_3} values). It is important to note that simultaneous replacement of native cysteines (the case of double mutant C63/123A) increased both water and ammonia permeabilities.

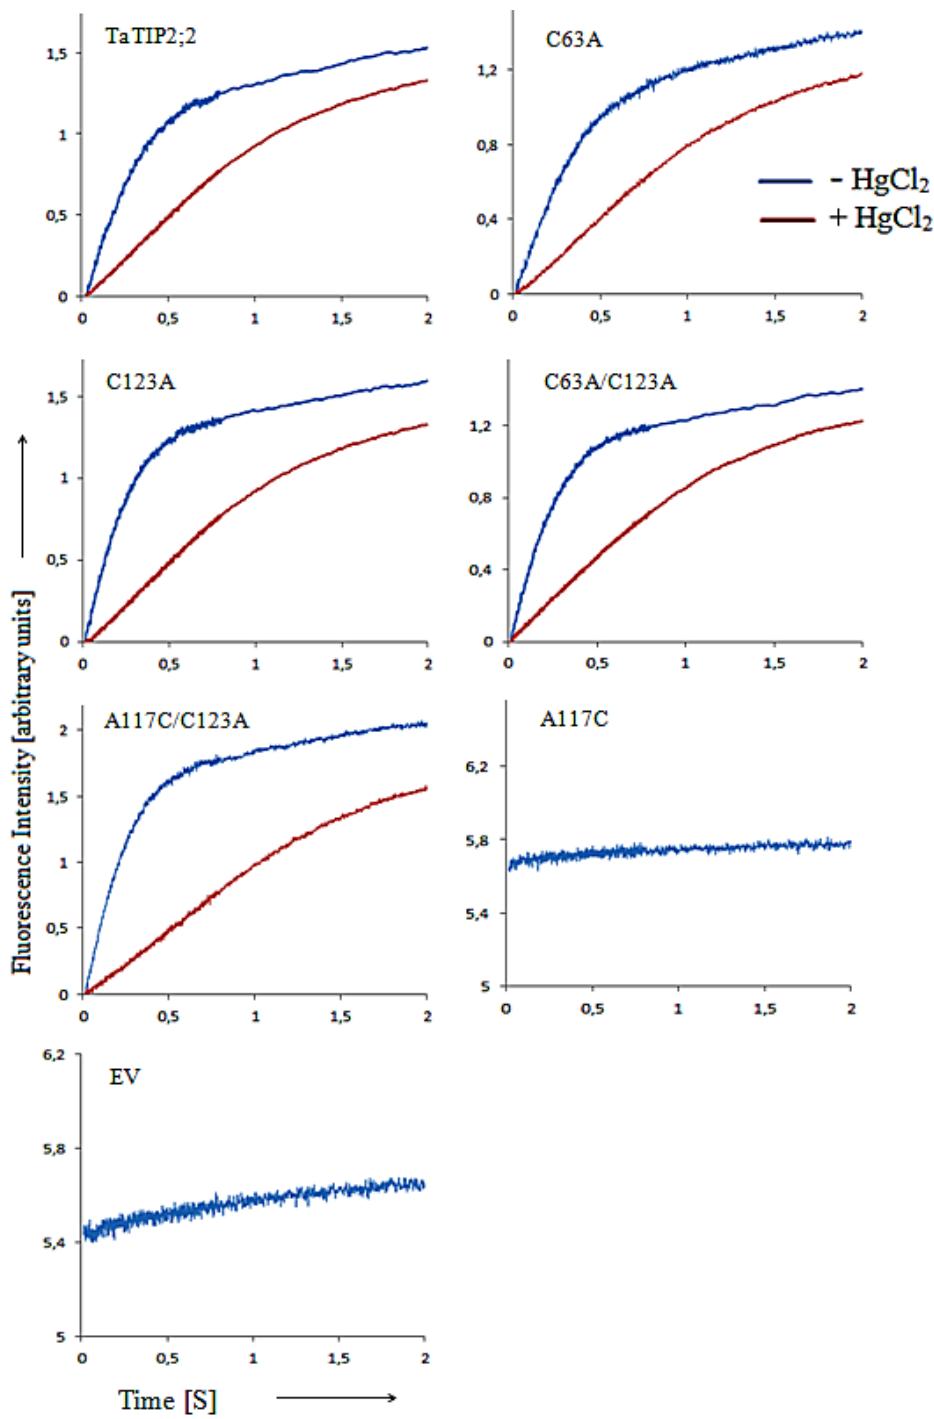

Fig 2.1.3: Ammonia permeability and its inhibition by mercury in *Saccharomyces cerevisiae*-yeast cells. The figure contains time courses of changes in fluorescence intensity in TaTIP2;2 and its mutants after subjecting the yeast cells to an outer solution containing 25mM NH₄Cl with and without preincubation with 1mM HgCl₂. All the time courses are presented after normalization, however the panel for A117C mutant shows a raw time course (without normalizing) due to the reason mentioned in the previous figure. Each trace is the average of 20-40 kinetics obtained from 3 individual experiments. The total number of traces acquired for each of the construct was at least 50. Note different scales along the y-axis. Also note that the followings are described in detail under separate captions in this chapter: (i) the investigations on Hg-sensitivity in TIP are described in detail under the caption 2.1.3, (ii) the Ala-to-Cys mutants (single and double) involve introduction of a Hg-sensitive site into TIP and are described in detail under the caption 2.1.3.1.

Cys63 is located in the transmembrane helix 2 which takes part in pore formation (Kjellbom *et al.*, 1999, Murata *et al.*, 2000). The TM2 in combination with TM5 adopts the mechanism of “fitting of ridges into grooves” and the two AQP1 helical bundles are locked together near the 4-fold axis of the tetramer (Murata *et al.*, 2000). A residue (Asn60) located in the middle of TM2 was reported to be involved in anion permeability of AQP6 (Liu *et al.*, 2005a). The ar/R region is widely believed to impart solute selectivity to the AQPs and is constituted by a tetrad of amino acids, one of which always belongs to TM2 (further details are given in Section 2.3 of results and discussion) (Gupta and Sankararamakrishnan, 2009).

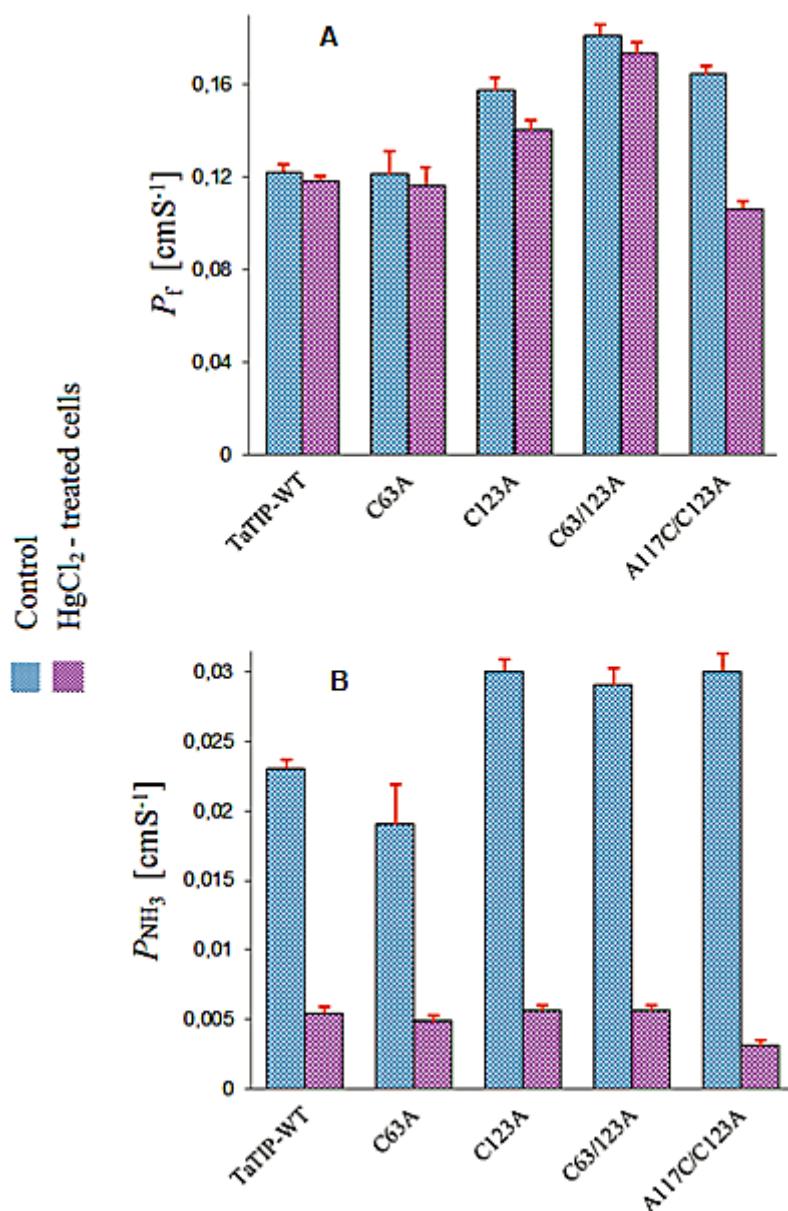

Fig 2.1.4: Coefficients of water (**A**) and ammonia (**B**) permeabilities determined in various mutants of TaTIP2.2 are presented in the bar chart. *Saccharomyces* protoplasts (in case of water permeability) or whole cells (in case of ammonia permeability) were treated with 1mM HgCl₂ for 5 min to determine the inhibitory effect. The data presented are the averages of 20-40 kinetics acquired from 3 individual experiments. The total number of

traces acquired for each of the construct was at least 50. Error bars indicate standard error of the mean. Note that the followings are described in detail under separate captions in this chapter: (i) the investigation on Hg-sensitivity in TIP is described in detail under the caption 2.1.3, (ii) the double mutant A117C/C123A involves introduction of a Hg-sensitive site into TIP and is described in detail under the caption 2.1.3.1.

The substitution of cysteines at positions 63 and 123 in combination increased water as well as ammonia permeabilities, which implies their role in solute permeability. The single mutant Cys63Ala, however, had P_f and P_{NH_3} values similar to the wild type. (Fig 2.1.4B, Appendix 1A, 1B). As no resolved structural data is available for the TIP sub-family of AQPs, a homology model of TaTIP2;2 was drawn to locate the positions of Cys residues using the “SWISS-MODEL” online tool. The tool performed a database-search for the availability of crystal structure of the closest homolog of the TaTIP2;2, which was hAQP4 (Tani *et al.*, 2009). This tool used crystal structure of AQP4 as template to provide the coordinates which were used to draw a model (Fig 2.1.5) which indicated that all the cysteines including Cys123 were located away from the pore and as such they seemed to have no role in influencing the pore dynamics and are unable to coordinate with the metals.

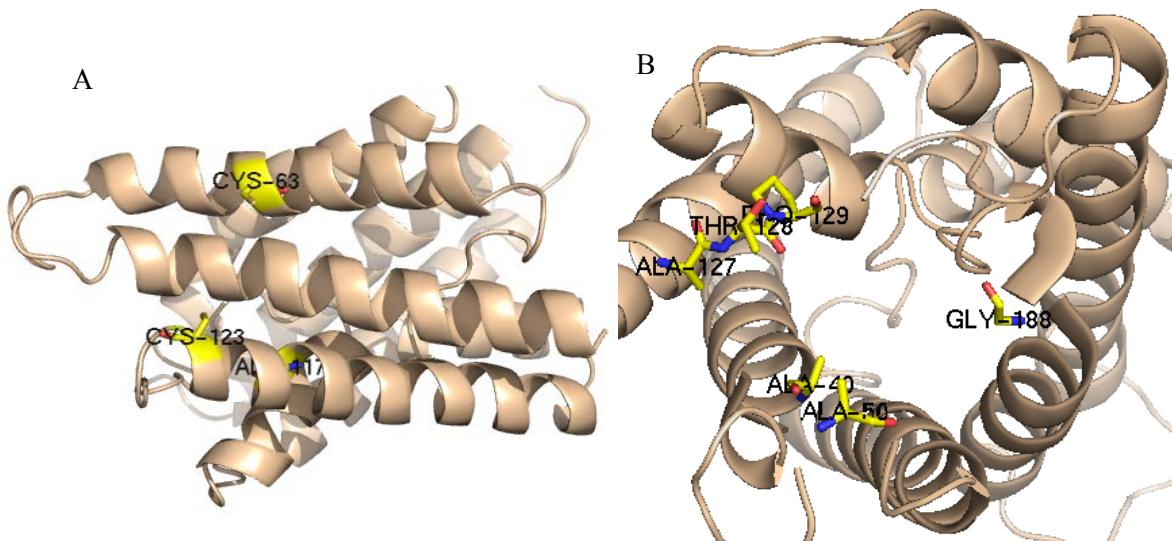

Figure 2.1.5: Homology models of TaTIP2;2 (**A**) A side view to show the location of native Cys63 and Cys123 residues in ribbon representation. Also shown is Ala117 which is homologous to Hg-sensitive Cys in γ -TIP. (**B**) The residues constituting the extracellular vestibule of the pore in TaTIP2;2-WT. Ala40, Ala50, Gly188, Ala127, Thr 128, Pro129 have been highlighted. The coordinates provided by the online tool “SWISS-MODEL” were used to draw the model in the software PYMOL. SWISS-MODEL used the hAQP4 crystal structure (PDB entry # 3GD8) as template.

2.1.3 Mercury sensitivity in TaTIP2;2

A typical feature of most of the AQPs characterized so far is their sensitivity against mercury. TaTIP2;2 is reported to be one of the several AQPs that are insensitive against mercury (Bertl and Kaldenhoff, 2007). In the present study, the single (Cys63 and Cys123) as well as the double (C63/123A and A117C/C123A) mutants were investigated for their sensitivity against mercury. The yeast protoplasts (in case of P_f determinations) and the whole cells loaded with fluorescein (in case of P_{NH_3} determinations) were subjected to mercury treatment prior to stopped-flow measurements. Surprisingly, in all the mutants, P_f remained unchanged (Fig 2.1.2, 2.1.4A) whereas P_{NH_3} was reduced by the mercury treatment (Fig 2.1.3, 2.1.4B). The optimal concentration required for the inhibition of ammonia transport was 1mM giving almost 80% inhibition after 5 minutes of pre-incubation with mercury. The pattern of inhibition in wild type as well as in all the mutants was comparable which implied that none of the cysteines had any role in inhibition and a common mechanism is responsible for the decrease in P_{NH_3} . The detailed comparison of P_{NH_3} values is given in Appendix 1B.

It was decided to thoroughly investigate the contrasting effect of mercury on P_f and P_{NH_3} . The yeast cells or protoplasts were preincubated with different concentrations of HgCl₂ to study the inhibition pattern against the concentration gradient of mercury and to determine the minimum possible concentration required for maximum inhibition of ammonia transport function. This experiment was performed only with the wild type TIP (no mutants were studied) and HgCl₂ concentration ranged from 1 μM to 5 mM. The normalized kinetics are presented in Fig 2.1.6. Regarding water permeability, none of the mercury concentrations had any effect on the mutants involving substitutions of native cysteines. However, the double mutant A117C/C123A exhibited a remarkable decrease in P_f (data are shown only for 1mM concentration in the present study). A detailed description of the results as well as a detailed account on the significance of Cys at position 117 will follow under the caption 2.1.3.1. A slight decrease in P_f observed in the case of mutant C123A is probably due to experimental artifacts as the double mutant C63/123A didn't show any inhibition.

In the case of ammonia permeability, increasing mercury concentration beyond 10 μM resulted in an increase in inhibitory effect on P_{NH_3} . The lowest concentration i.e. 1 μM had a rather slightly activating effect, whereas the highest concentration i.e. 5mM completely inhibited P_{NH_3} (Fig 2.1.6). The mercury inhibition took place in a concentration dependent manner and the rise of P_{NH_3} at 1μM Hg can be attributed to the changes in pore characteristics as such a low concentration is not expected to cause any toxic effect to the membrane (Loitto *et al.*, 2002). The modulatory effects,

irrespective of increase or decrease in P_{NH_3} , caused by very low concentrations of Hg indicate that a 1000 times higher concentration, i.e. 1mM may bring about some toxic effects.

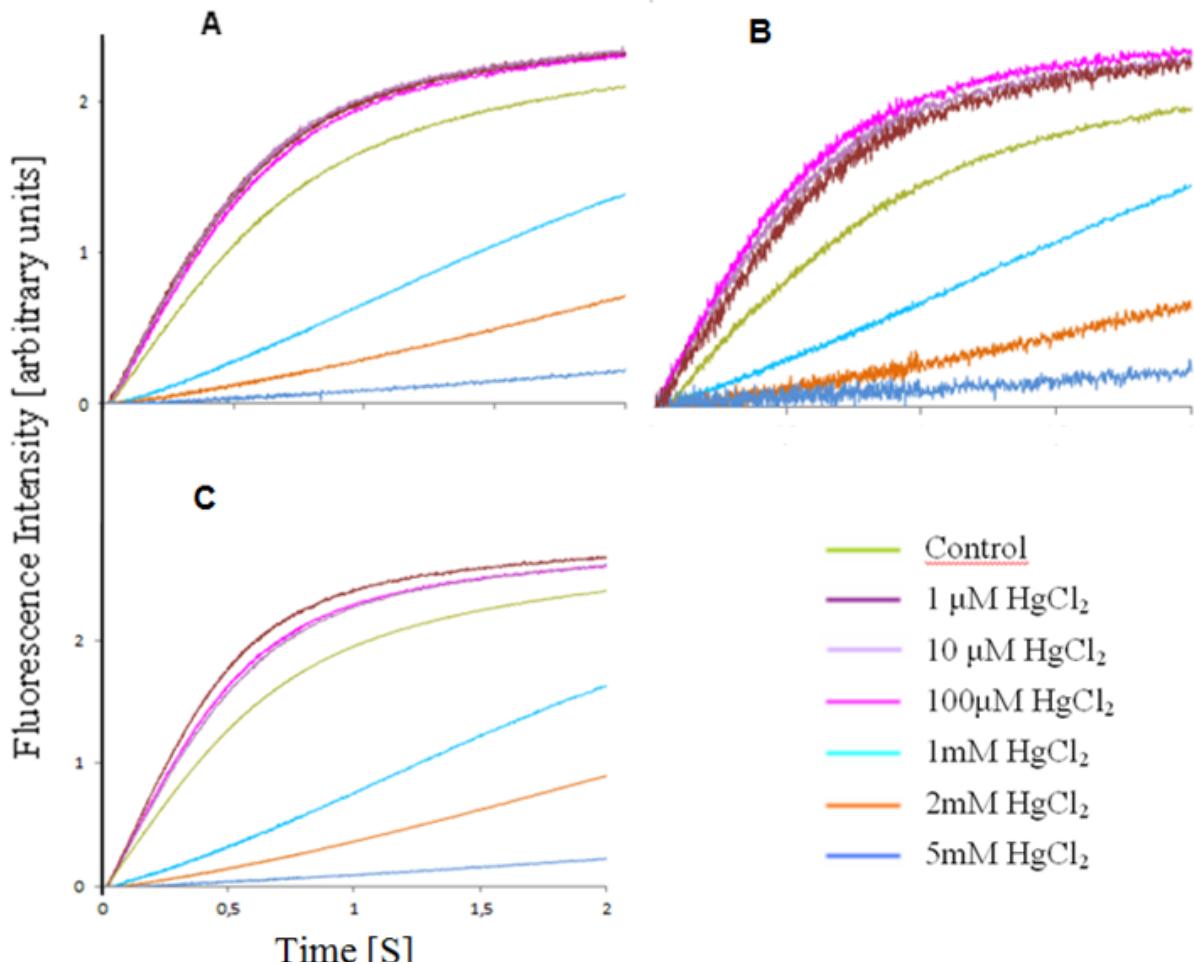

Fig 2.1.6: Ammonia permeability in *Saccharomyces cerevisiae* cells loaded with Fluorescein in (A) TaTIP2;2-wt (B) C63A and (C) C123A. The time courses represent changes in fluorescence intensity due to a rise in cytoplasmic pH after subjecting the yeast cells to an outer solution containing 25mM NH₄Cl. Each panel contains a set of kinetics obtained before (control) and after treatment with varying concentrations of HgCl₂. Only the rapid initial alkalinization phase is shown. Each trace is the average of 20-40 kinetics obtained from at least 3 individual experiments. The total number of traces acquired for each of the mercury concentrations (or the constructs) was at least 50. Note: Refer to Figure 2.1.3 for comparing the given kinetics with that obtained in the case of empty vector.

The homology model (Fig 2.1.5) suggests a distant location of all the native cysteines from the monomeric pore. The lack of sensitivity in the water pore may also be owing to any possible hindrance that prevents the access of Hg to the thiol

group of one of the Cys residues. The results, however, verify the lack of coordination site for metals (mercury in particular) in native TaTIP2;2 and also suggest, as expected, the structural similarity between the γ -TIP (TIP2;1) and the δ -TIP (TIP2;2). The sequences of the two TIPs show an identity of 60.7 % (sequence alignment is not shown).

The contrasting effect of $HgCl_2$ treatment on water and ammonia permeabilities can be explained on the basis of following evidences:

- (i) As the previous reports suggested, a central pore exists and ammonia is following this tetrameric pore instead of the water (monomeric) pore (Yool and Weinstein, 2002, Yu *et al.*, 2006, Bertl and Kaldenhoff, 2007). A supportive evidence was also provided by Niemietz and Tyerman (2000), who reported that both P_f and P_{NH_3} were reduced by Hg however, the inhibition of ammonia transport was 10x higher.
- (ii) Although molecular sizes of water and ammonia are similar (close to 3 \AA), there is a possibility that mercury changed the pore characteristics due to conformational changes in the protein. The altered pore may have imposed some selective hindrance on permeating solutes. The structural and functional studies in the T183C mutant (corresponding to Cys189 of AQP1) of bacterial AqpZ suggested that inhibition by mercury was merely because of steric hindrance in the pore as no conformational change in the protein was observed (Savage and Stroud, 2007). According to a contrasting report, mercury caused structural conformation resulting in the collapse of the ar/R region. The broken ar/R region in turn hindered the solute permeation. However, the presence of a steric mechanism could not be completely ruled out (Hirano *et al.*, 2010). It is speculated that different mechanisms of metal inhibition are prevailing in different AQP isoforms.

The phenomenon of decreased P_{NH_3} in the present study is based on parsimonious assumptions as the data can merely authenticate that inhibition is the result of the presence of mercury in the incubation buffer. In fact, the present study doesn't provide any concrete evidence to support coordination of mercury with Cys in TIP. Although a triple mutant with all the native cysteines knocked out (including Cys237 located in the C-terminal) is missing in the present study yet the fact that the native as well as the introduced Cys residues are equally accessible to Hg seems extremely unlikely.

2.1.3.1 Attempt to introduce a Hg-sensitive site in TaTIP2;2

As the TIP was lacking mercury sensitive Cys, it was decided to introduce a Cys from an already-known Hg-sensitive AQP at the homologous position in TIP. Fortunately, a close isoforms of TaTIP2;2 that is Arabidopsis TIP2;1 (commonly known as γ -TIP according to old nomenclature) has already been functionally characterized and reported to be sensitive to Hg, owing to a Cys located at position 118 (Daniels *et al.*, 1996). The corresponding position in TIP as suggested by the sequence alignment (Fig 2.1.7) was Ala117 located in transmembrane helix 3. The mutant Ala117Cys was nonfunctional for both water (Fig 2.1.2) and ammonia (Fig 2.1.3). The protein expression couldn't be determined due to the lack of appropriate antibody. It was attempted to produce monoclonal antibody against the TIP but it didn't show any affinity against the protein (data not presented). However, there was a convincing evidence available to believe that the protein in this mutant was expressed. In a double mutant where Ala117 was mutated to Cys and the nearby native Cys (position 123) was mutated to Ala, both water and ammonia transport functions could be observed (Figs 2.1.2, 2.1.3). The double mutant A117C/C123A exhibited significantly higher osmotic as well as ammonia permeability coefficients (Fig I.4). See Appendices 1A and 1B for a detailed comparison of P_f and P_{NH_3} values, respectively.

Fig 2.1.7: Partial sequence alignments to locate the Hg-sensitive residues in AQPs (indicated by asterisk). **(A)** A part of TM3 domain is aligned, which shows Hg-sensitive residue in gamma-TIP and its homologues in some functionally characterized plant AQPs. Note the homologous Alanine of TaTIP2;2 which has been substituted with Cys in the present experiment. **(B)** Alignment of a portion of the loop E sequences showing the well-characterized position of AQPs containing Hg-sensitive residues in various orthodox AQPs (belonging to mammals). Note this position is located N-terminal to the second NPA motif and has been referred to as “consensus region of metal sensitivity” in the present study.

The loss of function in case of the A117C mutant may possibly be attributed to the disulfide bonding between the two cysteine residues at positions 117 and 123. It is generally believed that the disulfide bridges enhance the conformational stability of a protein. However, some studies indicate that they are not always required for structural stability (Siddiqui *et al.*, 2005). Also, disulfide groups entropically destabilize the folded state by reducing the hydrophobic effect (Doig and Williams, 1991). The homology model (Fig 2.1.8), suggests that the distance between these positions is greater than required for any such interaction (Bondi, 1964). Both positions are located 6.9 Å apart from each other which is beyond the Van der Waals distance. In view of the model, disulfide-bridge formation between Cys117 and Cys123 seems unrealistic but it can't be verified based on the available experimental data.

It should have been attempted to breakdown the covalent bond by using a reducing agent such as DTT or β -mercaptoethanol. If there had been any function, it would have proved not only the expression of protein but also the absence of disulfide bonding between the concerned cysteines. It may also be possible that water permeability remained undetected. The water permeation phase which is quicker than that of gases might have elapsed before the photomultiplier begins to detect the signal. In case of ammonia conductance, however, it doesn't hold true because of the low affinity of AQPs for ammonia (Loque *et al.*, 2005, Holm *et al.*, 2005).

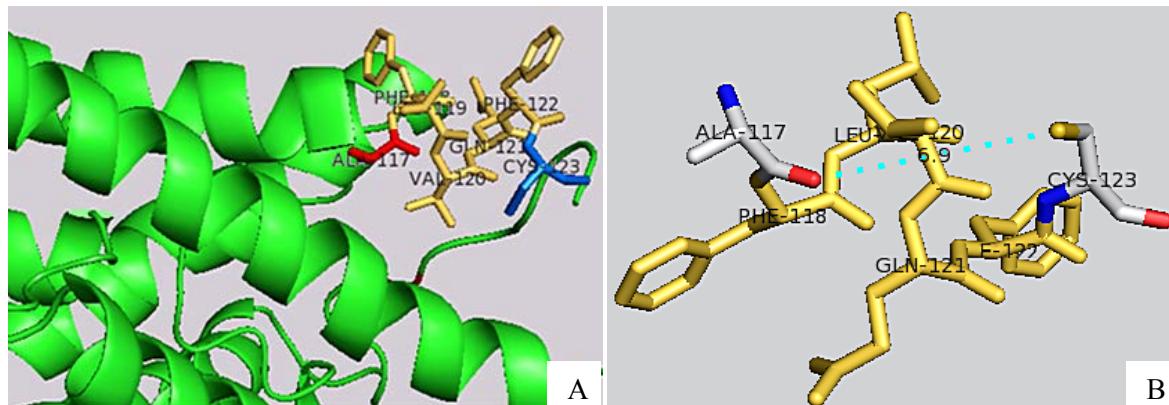

Fig 2.1.8: Homology models highlighting the positions 117 and 123 in TaTIP2;2. **(A)** A side view showing the environment around the two positions as a ribbon and stick representation. **(B)** Distance between the two positions in a figure showing Ca backbones and the side chains of various amino acids. The coordinates provided by the online tool “SWISS-MODEL” were used to draw the model in the software PYMOL. SWISS-MODEL used hAQP4 crystal structure (PDB entry # 3GD8) as template.

A. Metal sensitivity requires a Cys residue and this has to be at a particular position

It has been maintained for years that the metal sensitivity of an AQP is owing to the presence of functional groups available for metal coordination in the region located almost 3 residues N-terminal to the second NPA motif (in the loop E). Hg-sensitive residues are usually located in this region for instance, among orthodox aquaporins, Cys189 in AQP1 (Preston *et al.*, 1993), Cys181 in AQP2 (Bai *et al.*, 1996), Cys182 in AQP5 (Raina *et al.*, 1995), AQP8 because of Cys208 (Liu *et al.*, 2005b) and Cys213 in AQP9 (Ishibashi *et al.*, 1998). The importance of this region is further signified as the Cys residue at this position mostly also constitutes the ar/R region. AQP7 doesn't contain a Cys residue in this region and was reported to be Hg insensitive (Ishibashi *et al.*, 1997). Plasmodium aquaglyceroporin PfAQP (Hansen *et al.*, 2002) contains six cysteines but is still insensitive as none of them is located in the "consensus region". Introduction of Cys at this position imparts mercury sensitivity to the AQPs, which are otherwise insensitive. The mutant T223C was Hg-sensitive in the otherwise insensitive wild type *Arabidopsis* PIP2 (Daniels *et al.*, 1994). Recently, it was reported that AtPIP2;1 is inhibited by divalent cations with higher efficiency achieved with Ca^{2+} , Cd^{2+} and Mn^{2+} (Verdoucq *et al.* 2008). Although less is known about the potential region carrying metal sensitive residues in plant AQPs, NtAQP1 (Biela *et al.*, 1999), γ -TIP (Daniels *et al.*, 1996) and δ -TIP (Bertl and Kaldenhoff, 2007) were found to be mercury-insensitive.

Our study provides evidence supporting the presence of a "consensus region of metal sensitivity" in plants similar to that of mammalian AQPs. This region, at least in case of TIPs, is not located N-terminal to the second NPA motif, rather it is located in TM3. Whether a Hg coordination site can be introduced in this region throughout the plant AQPs should be investigated in future studies, no data is available even in well-characterized PIPs.

There are however some exceptions to the location of Hg-coordinating Cys residues. For instance, AQP3 is lacking any Cys in loop E and the sensitivity is because of Cys11 located in the N-terminus. It contains a Tyr residue at the position homologous to Cys189 of AQP1. The Cys substituted at this position increased Hg sensitivity. However, both P_f and P_{gly} were inhibited in a non-reversible manner (Kuwahara *et al.*, 1997). Also in the bacterial aquaporin AQPcic, the sensitivity is because of Cys82 located in loop B (Lagree *et al.*, 1998).

An interesting case is that of AQP4 which has been reported to be insensitive to Hg in oocytes (Yukutake *et al.*, 2004), but sensitive in liposomes (Yukutake *et al.*, 2008). The differences of sensitivity were because of varying orientations of loop D between oocytes and liposomes. The Hg sensitive site Cys178 was unusually located

in loop D. This site is normally inaccessible on the intracellular side however, it was reasoned that the membrane proteins in proteoliposomes are randomly oriented thereby 50% or more of the proteins are in access of mercury. The residue at the equivalent position in AQP1 is Thr157.

Although in rare cases, a Cys residue introduced at the position close to the “first” NPA motif might take the same charge as a Cys at the above-mentioned consensus region. Jung *et al.* (1994b) constructed a double mutant C189S/A73C of AQP1 the sensitivity of which was lower compared to the one exhibited by Cys 189 as the position 73 was located deep in the pore.

Surprisingly, AQP6 is rather activated by Hg (Yasui *et al.*, 1999) although it contains a Cys (position 190) homologous to the Hg-coordinating Cys189 of AQP1. It was found that Cys in this “consensus region” is one of the sites of mercury activation besides another Cys located in transmembrane helix 4, which might regulate the dynamic conformational changes in the channel (Hazama *et al.*, 2002). It is speculated that the mechanism of mercury binding is different in AQP6 as compared to other AQPs as mercury is not occluding in this case. Both conformational changes because of disintegration of the ar/R region (Hirano *et al.*, 2010) as well as steric hindrance in the pore (Savage and Stroud, 2007) are the mechanisms reported so far that bring about mercury inhibition in different aquaporins.

2.1.3.2 *Reversal of mercury inhibition by β-mercaptoproethanol*

The reducing agents when added to the cell suspension break the covalent interaction between thiol groups and mercury. In the present experiment, recovery of decreased P_{NH_3} was only 40% by 10 mM β-mercaptoproethanol (Fig 2.1.9). The lack of full recovery of ammonia permeability could be due to (i) the presence of more than one AQP isoforms (one sensitive to ME and the other not) or (ii) it could be caused by the toxic effects of $HgCl_2$ and/or ME (Zilli *et al.*, 2009).

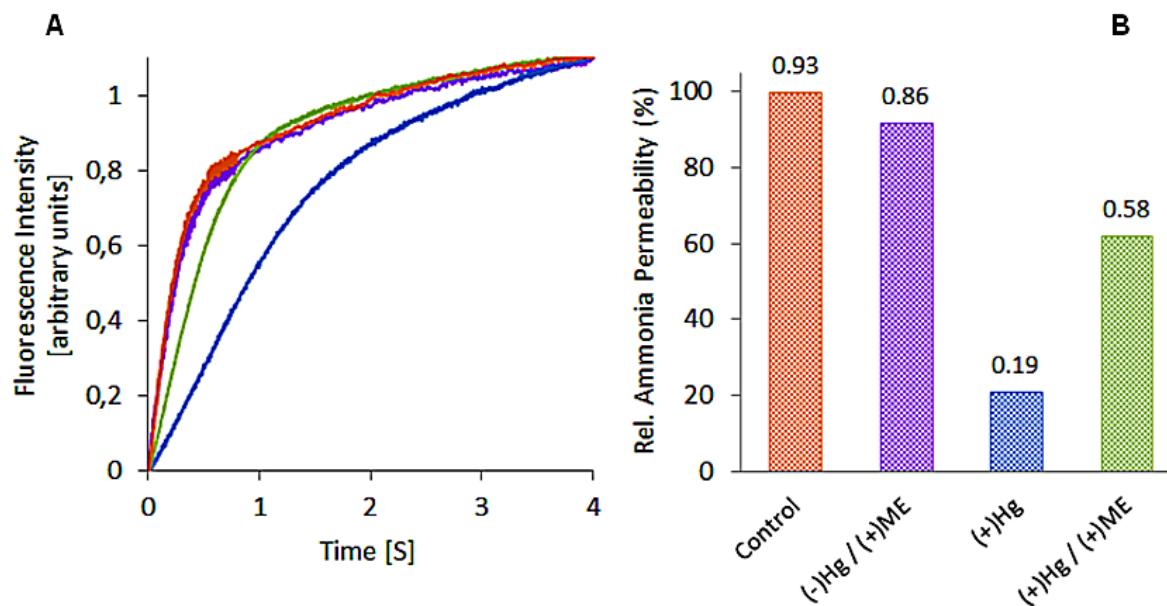

Fig 2.1.9: Reversal of mercury inhibition by 2-mercaptopethanol in TaTIP2;2-wt. *Saccharomyces* cells were pretreated with 1 mM HgCl₂ for 5 min or were pretreated with 1 mM HgCl₂ followed by incubation with 10 mM 2-mercaptopethanol for an additional 10 min and ammonia permeability was determined. **(A)** The time courses represent changes in fluorescence intensity due to rise in pH after subjecting the cells to an outer solution containing 25 mM NH₄Cl. Each time course is the average of 20–40 kinetics obtained from 3 individual experiments. The total number of traces acquired for each of the treatment was at least 50. **(B)** Coefficients of ammonia permeability for various treatments were calculated to present the reversal effect of 2-mercaptopethanol in terms of percentage of the control. The data labels on each bar represent P_{NH_3} value ($\times 10^{-2}$). Control represents the untreated cells.

The reversal of solute permeability was more than 50% in most of the AQPs for instance an AQP of *Trypanosoma cruzi* (Montalvetti *et al.*, 2004) and AQP3 (Watanabe *et al.*, 2005). In the former case, P_f was inhibited by both Hg and Ag to a similar extent. But in some cases it was just marginal (Yang *et al.*, 2006, Zilli *et al.*, 2009). γ -TIP was found to be marginally reversed by mercaptoethanol (Reizer *et al.*, 1993). The reversal was only marginal (less than 20%) in the plasmodium AQP mutant W124C located at the pore mouth (Beitz *et al.*, 2004). The reversal by β -mercaptopethanol was partial in case of AQP10 (Ishibashi *et al.*, 2002) and AQPcic (Le Cahérec *et al.*, 1996). There was no reversal at all in the case of sea bream AQP (Santos *et al.*, 2004).

ME recovered water transport only in sea bream AQP1a and not in sea bream aquaglyceroporin, suggesting different physiological roles of these AQPs (Zilli *et al.*, 2009). The lack of reversal by a reducing agent such as DTT or β -mercaptopethanol doesn't necessarily reflect the absence of interaction between sulfhydryl group and the cysteine. Podsiadlo *et al.* (2004), while studying inhibitors of proprotein convertase, proposed that irreversibility of Zn inhibition is caused by a

combination of poor lability of the Zn to aromatic nitrogen bond and to blocking of the pathway for ligand exchange on metal after binding to the protein.

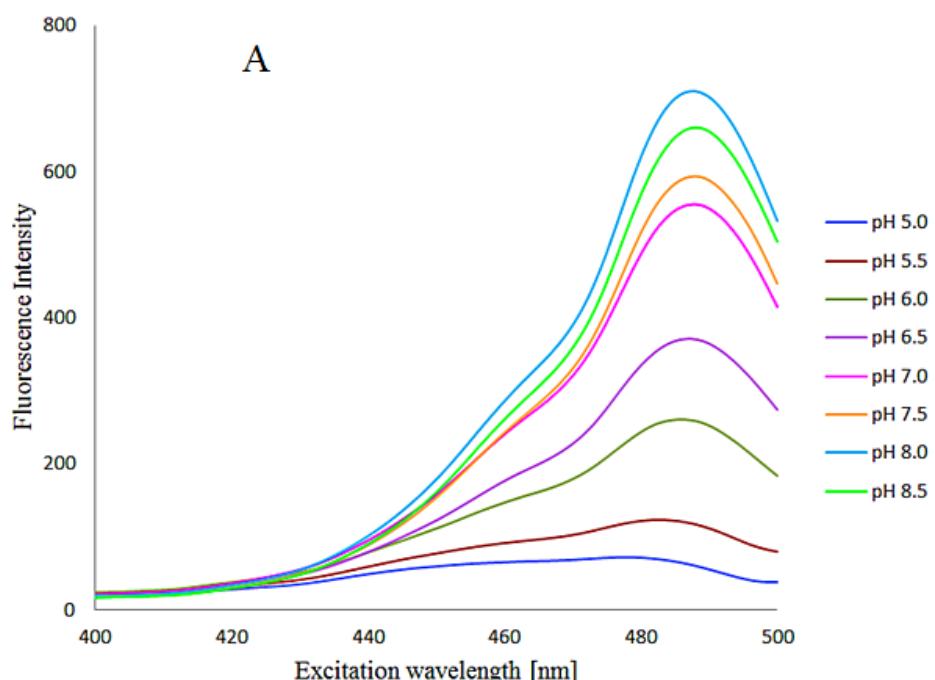

2.1.4 Estimation of cytosolic pH

This experiment was aimed at estimating the rise in pH of *Saccharomyces* cells as a result of ammonia influx in the functional studies. For this reason, a calibration curve was drawn by exploiting the pH-dependent changes in fluorescence intensities of an appropriate dye namely Fluorescein. The ratios of the fluorescence intensities acquired at 490nm and 430nm excitation were calculated. The ratios were plotted against the corresponding pH to get the calibration curve as shown in Fig 2.1.10.

The cytosolic pH values obtained using the given method are merely apparent (and not absolute) values. The yeast cells were loaded with Fluorescein and changes in fluorescence intensities were determined both before and after mixing with the outer solution containing NH₄Cl. Using the calibration curve, pH values corresponding to the given fluorescence intensities were estimated and are given below:

Apparent cytosolic pH before mixing with outer solution	6.73
Apparent cytosolic pH after mixing with outer solution	7.15
Apparent rise in pH	0.38

The ratios of fluorescence intensities acquired at two distinct excitation wavelengths are plotted in a calibration curve as ratiometric measurements eliminate potential artifacts. The artifacts may arise due to the loss of intracellular fluorescent agent, changes of cell thickness during an experiment, changes in detector sensitivity etc.
[\(<http://www.teflabs.com/ion-indicators>\)](http://www.teflabs.com/ion-indicators)

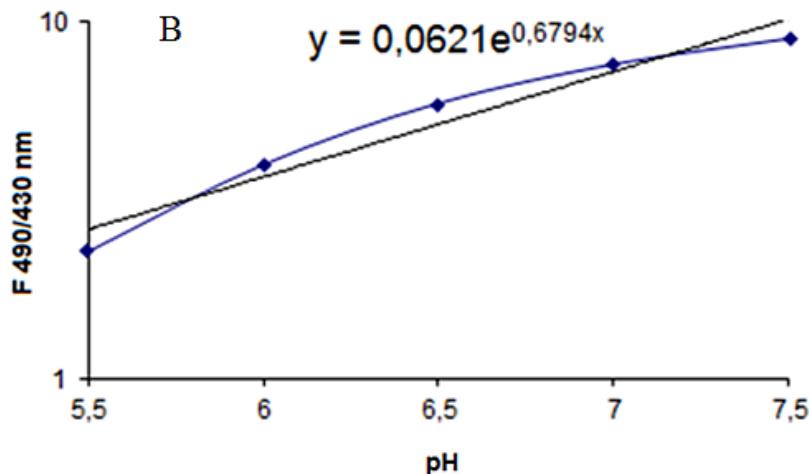

Fig 2.1.10: Fluorescence excitation spectra of *Saccharomyces* cells loaded with Fluorescein in various pH-adjusted buffers were determined with a spectrofluorimeter. (A) The fluorescence intensities were acquired at excitation wavelengths between 400 and 500 nm, and the emission was collected at 520nm. (B) *In vitro* calibration curve presented as a logarithmic plot of the ratio of fluorescence emission at 520nm with excitations of 430nm and 490nm, versus pH of the buffer. Values are the means from triplicate determinations.

2.1.5 Effects of Cu²⁺ and Ni²⁺ preincubation on TIP function

In order to further investigate the contrasting inhibition response between water and ammonia permeabilities in TIP, other heavy metals like Cu²⁺ and Ni²⁺ were also employed. In this experiment, however, only the wild type TIP was pre-treated with the metals. Ni²⁺ didn't exert any inhibitory effect on P_f (Fig 2.1.11) or P_{NH_3} (data not shown) whereas Cu²⁺ exhibited the similar outcome as in the case of mercury. P_f was not inhibited by Cu²⁺, but P_{NH_3} followed a concentration-dependent inhibitory pattern similar to the one observed under mercury treatments (Fig 2.1.12). The native TIP contains no Cys at the required location, hence it didn't exhibit any inhibition of P_f . It would have been interesting to test mercury, copper and nickel also on the double mutant containing a Hg-sensitive Cys that is A117C/C123A. As such, this experiment couldn't contribute to elucidate the mechanism of inhibition in TIP but it verified the following phenomena: (i) The decrease in P_{NH_3} was intrinsic to the influence of Hg²⁺ or Cu²⁺. (ii) Whatever the underlying mechanism could be, it would be the same in case of both Cu²⁺ and Hg²⁺.

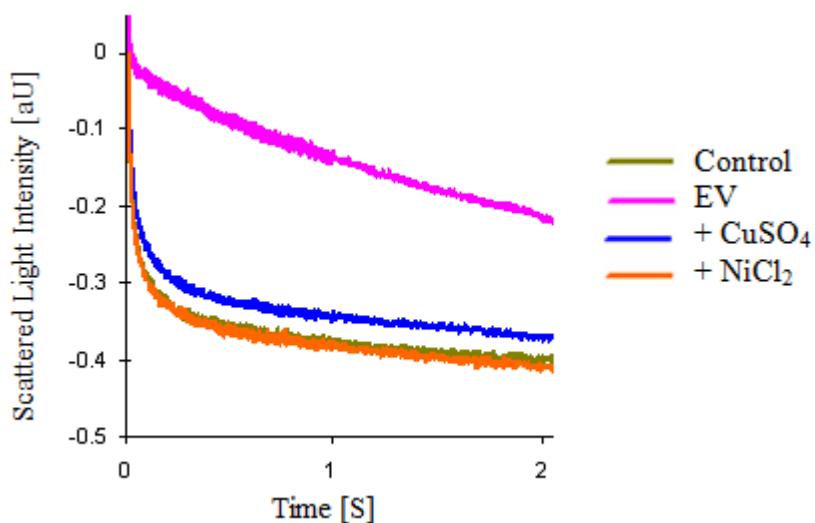

Fig 2.1.11: Inhibition of osmotic permeability due to copper and nickel in protoplasts of *Saccharomyces cerevisiae* yeast cells. The figure contains time courses of changes in scattered light intensity in TaTIP2;2-wt after subjecting the yeast cells to a hypoosmotic shock of 300 mosmol. For studying the effect of metal inhibition, yeast cells were incubated with 1mM of CuSO₄ or NiCl₂. Each time course is the average of 20-40 kinetics obtained from 3 individual experiments. The total number of traces acquired for each of the given metals was at least 50. Control stands for untreated TaTIP2;2-wt cells, whereas EV stands for empty vector.

No particular study was carried out to assess the accessibility of metals. However, the fact that the inhibition by HgCl₂ was partially reversible in wild type TIP indicates that the native cysteines were accessible to mercury. However, no data concerning the reversibility of Cys mutants is available hence the present study can't distinguish various Cys residues with regard to their accessibility. Distant location of all the native cysteines from the "consensus region of sensitivity" as well as the homology model (Fig 2.1.5) further ambiguates the issue of accessibility of heavy metals.

The chances of damage to the membrane because of mercury (and not any non-specific effect) can't be completely ruled out in this study. The reason being that the phenomenon of mercury inhibition was though reversible by β-mercaptoethanol, it occurred to a smaller extent compared to what has been reported in previous studies. The literature reports preincubation of AQPs with even as high as 3mM concentration of HgCl₂ (Mitani *et al.*, 2008) and its full recovery (Rivers *et al.*, 1997) indicating that toxic concentrations of Hg vary among various proteins.

All the metals employed in the present study carry a net positive charge however, molar volume of Ni is less than Hg and Cu. Copper is able to act on aquaporins extracellularly (Zelenina *et al.*, 2004), whereas mercury has to penetrate through the membranes to inhibit. Copper and nickel exhibited contrasting inhibition response

despite similarity in their molar volumes (7.11 and $6.59\text{ cm}^3/\text{mol}$, respectively). Likewise, mercury which is bigger in size ($14.8\text{ cm}^3/\text{mol}$) than the other two metals gave similar inhibition pattern as did the copper. Therefore it can be concluded that size and charge of the metals are not the only crucial factors determining their accessibility to the ligands and the subsequent coordination (Pelis *et al.*, 2007).

Binding of the transition metals doesn't always follow a set of general principles, therefore the mechanism involved in a particular protein should be investigated as an individual case. The soft metals (e.g., copper, cadmium, mercury) preferentially bind to ligands containing sulfur as the sulphydryl group. The hard metals (e.g., calcium, sodium, iron, magnesium) prefer to bind to ligands containing oxygen over sulfate and phosphate functional groups (Sandrin and Hoffman, 2007). Cu^{2+} is capable of binding with the imidazole of His and the thiol of Cys (Banci *et al.*, 2009, Duncan *et al.*, 2006). Ni^{2+} can also effectively bind to the sulphydryl group of Cys (Desrochers *et al.*, 2007, Kozlowski *et al.*, 1987).

Mercury has a higher affinity to cysteine than copper and nickel (Bremner and Beattie, 1990). The sulphydryl group of cysteine may also coordinate with other metals like Zn (Schumacher *et al.*, 1998), copper and iron (Yukutake *et al.*, 2009). The heavy metal ions were found to inhibit the activity of urease in the following order $\text{Hg}^{2+} > \text{Cu}^{2+} > \text{Cd}^{2+}$ (Tsai and Doong, 2005).

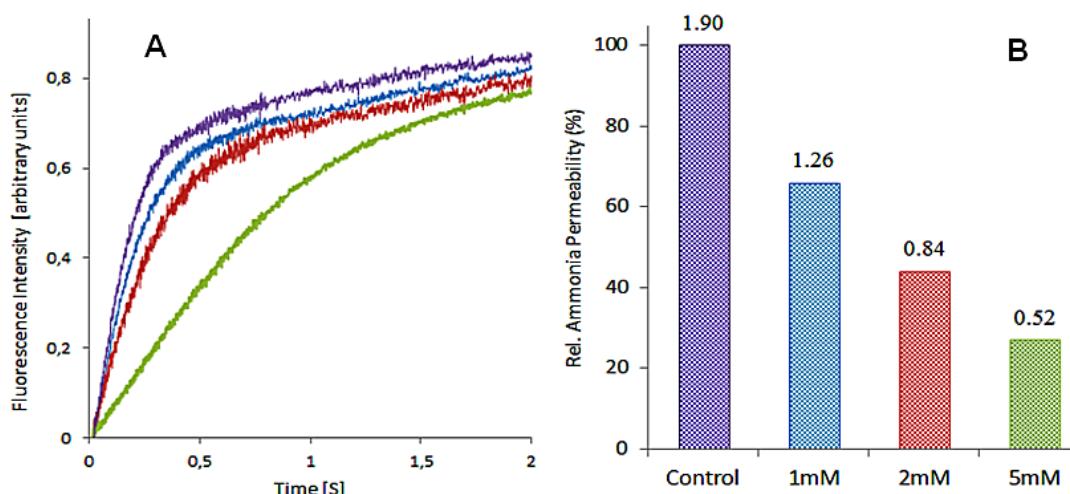

Fig 2.1.12: Inhibitory effect of copper on ammonia permeability in TaTIP2;2-wt. *Saccharomyces* cells were treated with 1 mM CuSO_4 for 5 min before ammonia permeability was determined. (A) The time courses represent changes in fluorescence intensity due to rise in pH after subjecting the cells to an outer solution containing $25\text{ mM NH}_4\text{Cl}$. Each time course is the average of $20\text{--}40$ kinetics obtained from 3 individual experiments. The total number of traces acquired for each of the concentration employed in this experiment was at least 50 . (B) Coefficients of ammonia permeability for various treatments were calculated to present the inhibitory effect of various concentrations of copper in terms of percentage of the control. Control represents the cells not preincubated with copper. The data labels on each bar represent P_{NH_3} value ($\times 10^{-2}$).

Copper is a trace element essential to life. Its role in enzyme catalysis and gene expression is well established. Binding of copper to the Cys-binding domains in the N-terminal is required for protein-protein cooperativity in a P-type ATPase (Banci *et al.*, 2007). The copper-transporting ATPases coordinate with copper through a mechanism involving two Cys residues found in the MXCXXC motif (Ralle *et al.*, 2004). Another P-type ATPase also contains a MTCAAC binding motif which plays a role in the resistance of the cell to copper by affecting the export of the metal across the cell membrane (Singleton *et al.*, 2008).

Copper and nickel may become an important tool in pharmacological interventions because of their quick and reversible effects on biological molecules. Zelenina *et al.* (2003) reported similarity in the mechanism of inhibition by Cu and Ni as the same residues were involved in P_f and P_{gly} inhibition in response to both metals. Three amino acid residues in the second and the third extracellular loops, Trp128, Ser152, and His241, were shown to be involved in the copper-mediated AQP3 inhibition. P_{gly} (but not P_f) in AQP4 was inhibited by copper. Ni inhibited AQP3 but not AQP4 and AQP5. In AQP0, copper had no effect but nickel was found to increase the P_f (Nemeth-Cahalan *et al.*, 2007).

Silver and gold also inhibited the osmotic permeability in AQPs of mammals and plants origin; the former was more effective than Hg, but not reversible by reducing agents (Niemietz and Tyerman, 2002). The mechanism of inhibition was however not described. The widely-studied AQP1 is also inhibited, apart from mercury, by TEA. This inhibition is associated with Tyr186 residue located in loop E, which doesn't directly coordinate with TEA, rather it gives structural flexibility essential for the inhibitory effect (Detmers *et al.*, 2006). In oocytes expressing AQP3, water and urea permeabilities were partially inhibited by 0.1 mM phloretin and 0.3 mM HgCl₂ (15–20%), whereas glycerol permeability was unchanged (Tsukaguchi *et al.*, 1998).

2.1.6 General Discussion

Cys and Ala both are nonpolar and hydrophobic amino acids. The Cysteine to Alanine mutation does not dramatically alter the side-chain polarity, length, or volume therefore minor changes in terms of solute permeabilities in the Cys-to-Ala single mutants could easily be comprehended.

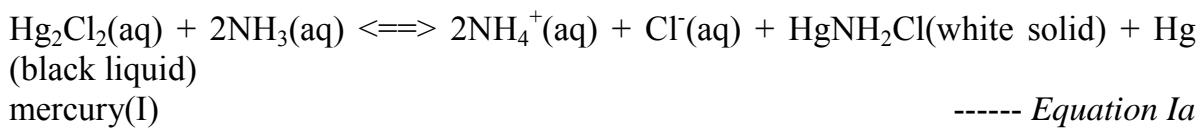

Two modes of how proteins are affected by metal ions have been described to date: the metal ions either bind to free thiol and other functional groups of certain native proteins or replace zinc and other essential metal ions in metal-dependent proteins (reviewed by Sharma *et al.*, 2008). Metal ions are particularly inclined to bind with the functional groups of amino acid side chains for instance, the carboxylate groups

of Asp and Glu, and the ring nitrogen of His. However, the metals may also bind to the side chains for instance, ring nitrogen of Trp, thiol group of Cys, hydroxyl groups of Ser, Thr, Tyr etc (Glusker *et al.*, 1999).

Inorganic mercury and other heavy metals used in this study share some common features which have been mostly investigated while studying metalloproteins. Hg, Cu and Ni are all membrane-permeant metals. The ability of only mercury and copper and not of Nickel to inhibit P_{NH_3} can't be explained with the given results. Differences in the mechanism of various heavy metal inhibitors have already been reported. The preferential site for Ni^{2+} binding in AQP3 was a Histidine (Zelenina *et al.*, 2003). In hAQP1 and a plant NIP, the metals Cu, Ni and Cd had no effect but silver and gold inhibited the water permeability. Further, silver and mercury were proposed to have different mechanism as inhibition by the former was not reversed by the application of mercaptoethanol (Niemietz and Tyerman, 2002).

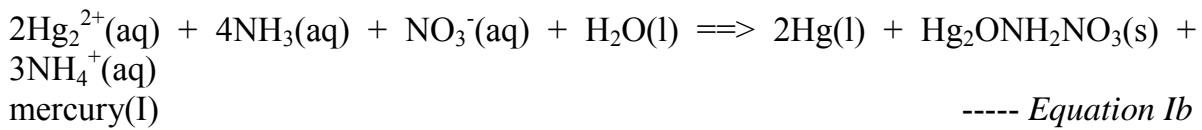

Most metal ions react with electron-pair donors to form coordination compounds or complexes. Copper (II) has a coordination number of four. Copper when complexed with ammonia results in a cationic complex, $\text{Cu}(\text{NH}_3)_4^{2+}$. Likewise, mercury can also form complexes with ammonia through the following chemical reactions:

Aqueous ammonia, through the following oxidation-reduction reaction with mercury(I), would yield a fine dust of black metallic mercury and white amido salt:

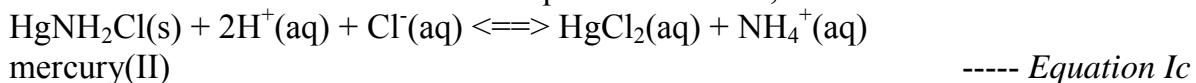

or

Aqueous ammonia would yield a mixture of metallic mercury and a white basic amido salt

These salts are not soluble in excess aqueous ammonia, but do dissolve in acids.

Because of the above-mentioned mercury-ammonia complex formation, the amount of ammonia available at the pore entrance would decrease. It may have reflected in terms of a decrease in ammonia permeability. Despite complexing of mercury with ammonia, the decrease in P_{NH_3} after Hg treatment may still be attributed to the

Cys–Hg coordination. A remarkable clue in this direction was that the inhibition by HgCl_2 was reversible, though merely to an extent of 40%. As the protoplasts were treated with a concentration as high as 1mM, it might have inflicted a non-specific effect on TIP. It must be noted that cell viability decreases with time and the value obtained is definitely under-estimated. As discussed earlier in this section, the recovery after mercury inhibition was never reported to be 100%; in some cases it was rather marginal. The issue was, however, not further investigated. Stoichiometric studies for the above-mentioned reaction (at varying concentrations of ammonia and mercury) as well as resolving the structure of TIP would help in understanding the fate of mercury and ammonia.

AQP3 inhibition by copper is principally different from inhibition by mercury, which is also a divalent heavy metal. Mercury binds covalently to the proteins therefore the effect of mercury is reversed only by using a reducing agent, such as β -mercaptoethanol. In contrast, copper forms coordination bonds with proteins and the effect of copper is reversed by simple washout of the metal ions (reviewed by Zelenina *et al.*, 2004). Even in case of mercury agents, the molecular mechanism of inhibition may vary among the AQPs as proposed in AQP1 and AQP4 (Yukutake *et al.*, 2009).

The similar pattern of inhibition by Hg and Cu in the present study highly disfavors the concept of an independent central pore for gas permeation. Mercury inhibition of ammonia permeability has already been reported in NOD26 (Niemietz and Tyerman, 2000) and TaTIP2;2 (Bertl and Kaldenhoff, 2007). As P_{NH_3} but not P_f was affected by mercury, two independent pathways were proposed for water and ammonia conductance. Some evidences suggest that gases may pass exclusively through the tetrameric pore of AQPs (Yool and Weinstein 2002, Yu *et al.*, 2006). The phenomenon of coordination of mercury with ammonia needs immediate attention so that the said discrepancy between contrasting inhibition of water and ammonia could be solved. Such an ambiguity was further enhanced by the fact that all the three Cys-to-Ala mutants exhibited similar inhibition pattern. All the native cysteines in TIP2;2 are not expected to be projecting into the pore. Also the presence of all cysteines at equally-accessible position seems extremely unlikely (see homology model of TaTIP2;2 in Fig 2.1.5).

2.1.7 Conclusions

The present study aimed at determining the Hg-sensitive site in TaTIP2;2. In the mutational analysis, a series of single and double mutants were generated replacing the native Cys residues in a sequential manner. Besides mercury, copper and nickel

were also employed to get a deeper insight of the inhibitory mechanism in TIP. Unfortunately, because of contradictory results, the present study is too restricted to shed light on the location of Cys residues and even on the accessibility of heavy metals to these residues.

The following inferences could be drawn based on the results obtained:

- (i)** None of the native Cys residues played any remarkable role in the pore structure or function of the TIP. However, keeping in view the osmotic permeability of the double mutant A117C/C123A (which is higher than the wild type TIP), it is tantalizing to propose that the substituted Cys projects into the pore and is capable of modulating the solute permeability. This phenomenon implies similarity in the structure of γ and the δ -TIP.
- (ii)** Present results support the existing postulate that usually both Cys and its position are necessary to impart mercury sensitivity to an AQP. At least in TIPs, if not true for the entire plant AQPs, there may exist a “consensus region of metal sensitivity” in TM3, which is analogous to the one present in mammalian AQPs. However, Hg sensitivity can't be considered as a phenomenon based on a certain uniform mechanism across the family of AQPs and ideally it requires thorough investigation involving the reconciliation of functional data, Cys scanning analysis (focusing the region near to NPA motifs), structural data about apo- and Hg-bound forms of the protein etc.
- (iii)** The present results do not provide any concrete evidence either supporting or against the existing view of presence of a separate gas pore in AQPs. The selective monomeric and tetrameric pore inhibitors may be helpful in this regard for future studies. In case the central pore exists in AQPs at all, it is blocked by cadmium, but not by TEA (Yu *et al.*, 2006), whereas the water pore is blocked by TEA and not by cadmium (Jung *et al.*, 1994a).
- (iv)** The discrepancy of similar inhibition by mercury and copper (as against nickel) couldn't be solved and the involvement of some other metal-coordinating residues/sites may be given due attention in future studies.

2.2 Molecular determinants of selectivity in AQPs: *Investigations outside the selectivity regions*

This section involves a comprehensive mutational analysis to study the molecular determinants of ammonia selectivity. As discussed in chapter 1, the determinants of ammonia selectivity are extended beyond the selectivity filter and the NPA region in aquaporins. The experiments presented in this section involved the identification of the unique residues (apart from the constituents of the above-mentioned constrictions) and studying their role in the ammonia transport function of the protein by adopting site directed mutagenesis approaches. The aims of this study are summarized as follows:

- (i) identifying the molecular signatures taking part in the selective recruitment of ammonia in the pore, (ii) an attempt to convert an ammonia impermeable AQP into an ammonia permeable AQP (and vice versa) by focusing on these molecular signatures and (iii) to have some insight into the mechanisms of substrate specificity and ammonia conductance in AQPs.

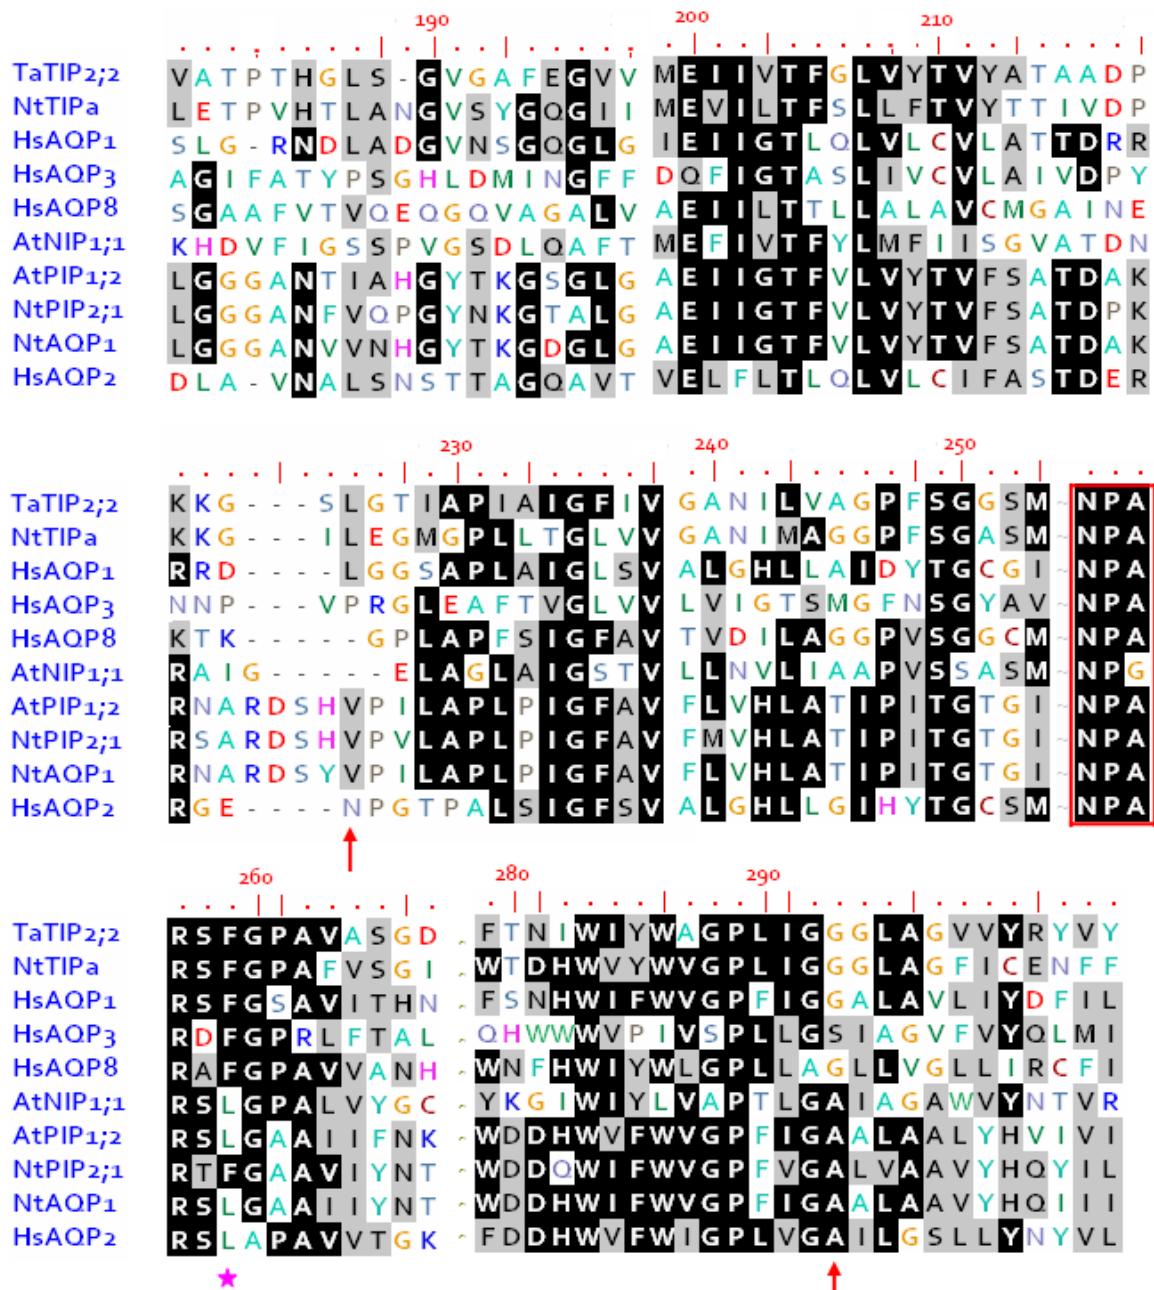

2.2.1 Identification of molecular signatures potentially relevant for selectivity

Sequences of some of the aquaporins, the ammonia permeability of which has already been characterized, were aligned (Fig 2.2.1). The aquaporins included in the alignment belong to plants (TIPs, PIPs and NIP) and mammals (AQP1, 2, 3 and 8). According to the alignment, some of the residues appeared to be unique between the ammonia-conducting and non-conducting plant AQPs. The identified amino acid signatures were also observed in some of the mammalian AQPs. One candidate each from ammonia facilitating and non-facilitating plant AQPs that is (respectively) TaTIP2;2 and NtPIP2;1 were selected for the present experiment. The prospective residues were: Ile97, Leu168 and Gly224 in case of TaTIP2;2, whereas in case of NtPIP2;1, the corresponding residues were Val117, Val197 and Ala256. The respective positions will be hereafter referred to as position I, II and III.

Fig 2.2.1: Sequences of various AQPs, the ammonia permeability of which is already reported, have been aligned. TaTIP2;2, NtTIPa, HsAQP1, HsAQP3, HsAQP8 and AtNIP1;1 are reported to be ammonia transport-facilitating, the rest are non-facilitating. The NPA motifs are boxed in red lines. Red arrows indicate the residues which were distinguished between ammonia transport-facilitating and non-facilitating AQPs. The position indicated by a pink asterisk might be a prospective candidate for future studies to determine the molecular signatures of AQP-facilitated ammonia permeability. The breaks (denoted by ~) represent discontinuity where a blank portion in the alignment was eliminated. Numbering is arbitrary and doesn't represent any of the given sequence. The alignment was generated using the BioEdit software that incorporates the multiple sequence alignment tools of ClustalX.

(Sequence alignment continued from previous page)

2.2.2 Molecular signatures of selectivity in NtPIP2

2.2.2.1 Mutational analysis

Focusing on the set of amino acid positions as indicated by the sequence alignment, it was attempted to convert the ammonia-tight NtPIP2;1 aquaporin into an ammonia transport facilitating one. This experiment included following point mutations: substitution of Val117 by Ile, Val197 by Leu, and Ala256 by Gly. The mutants Val117 (Position I), Val197 (Position II) and Gly256 (Position III) are located in loop B, loop D and transmembrane helix 6, respectively. Two double mutants that is V117I/V197L and V197L/A256G and a tripe mutant V117I/V197L/A256G were also generated. All the given mutants were devoid of any ammonia permeability; the raw time courses of changes in fluorescence intensity are presented in Fig 2.2.2. The kinetics were not normalized (against each other or against a standard curve) as normalizing the nonfunctional curves elevates the initial brief but fast component (always found in such curves) to several orders of magnitude; a fact which might be considerably misleading in such functional experiments.

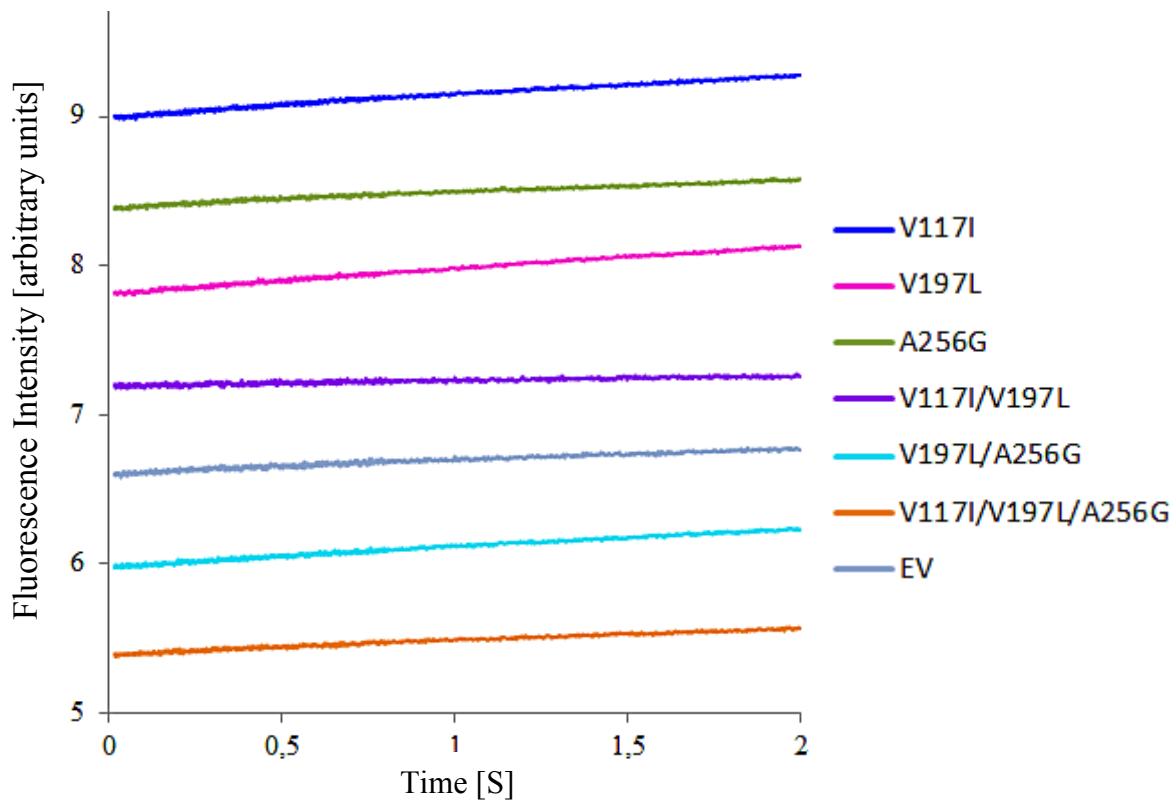

Fig 2.2.2: Time courses of ammonia permeability in various mutants of NtPIP2;1. Each time course is the average of at least 20– 40 kinetics obtained from at least 3 independent experiments. The total number of traces acquired for each construct was at least 50. The raw kinetics are presented without normalization. TaTIP2;2 which is an ammonia-conducting AQP served as positive control in this experiment (data not shown in this figure but given elsewhere).

In contrast to the TaTIP2;2 (results given later in this section), point mutations of homologous residues in NtPIP2 exhibited drastic changes in water permeability. The raw traces (without normalization) are given in Fig 2.2.3. All mutants proved to be different as compared to the wild type PIP2. The osmotic permeability coefficient in V117I was higher (183%), whereas that of the other two point mutations V197L and A256G was much lower (62% and 52%, respectively) than the wild type (Fig 2.2.4). The previously mentioned double mutants were also studied, which included a combination of (i) one faster (compared to WT) and one slower mutant (V117I/V197L) and (ii) both of the slower mutants that is V197L/A256G. The former double mutant V117I/V197L, as expected, was not much different from the wild type (83% of PIP2-WT) and the latter double mutant V197L/A256G was nonfunctional (data not shown). The triple mutant where Val117, Val197 and Ala256 were substituted by Ile, Leu and Gly, respectively, showed a P_f of 30% of the wild type PIP2. See Appendix 1C for detailed P_f values comparison.

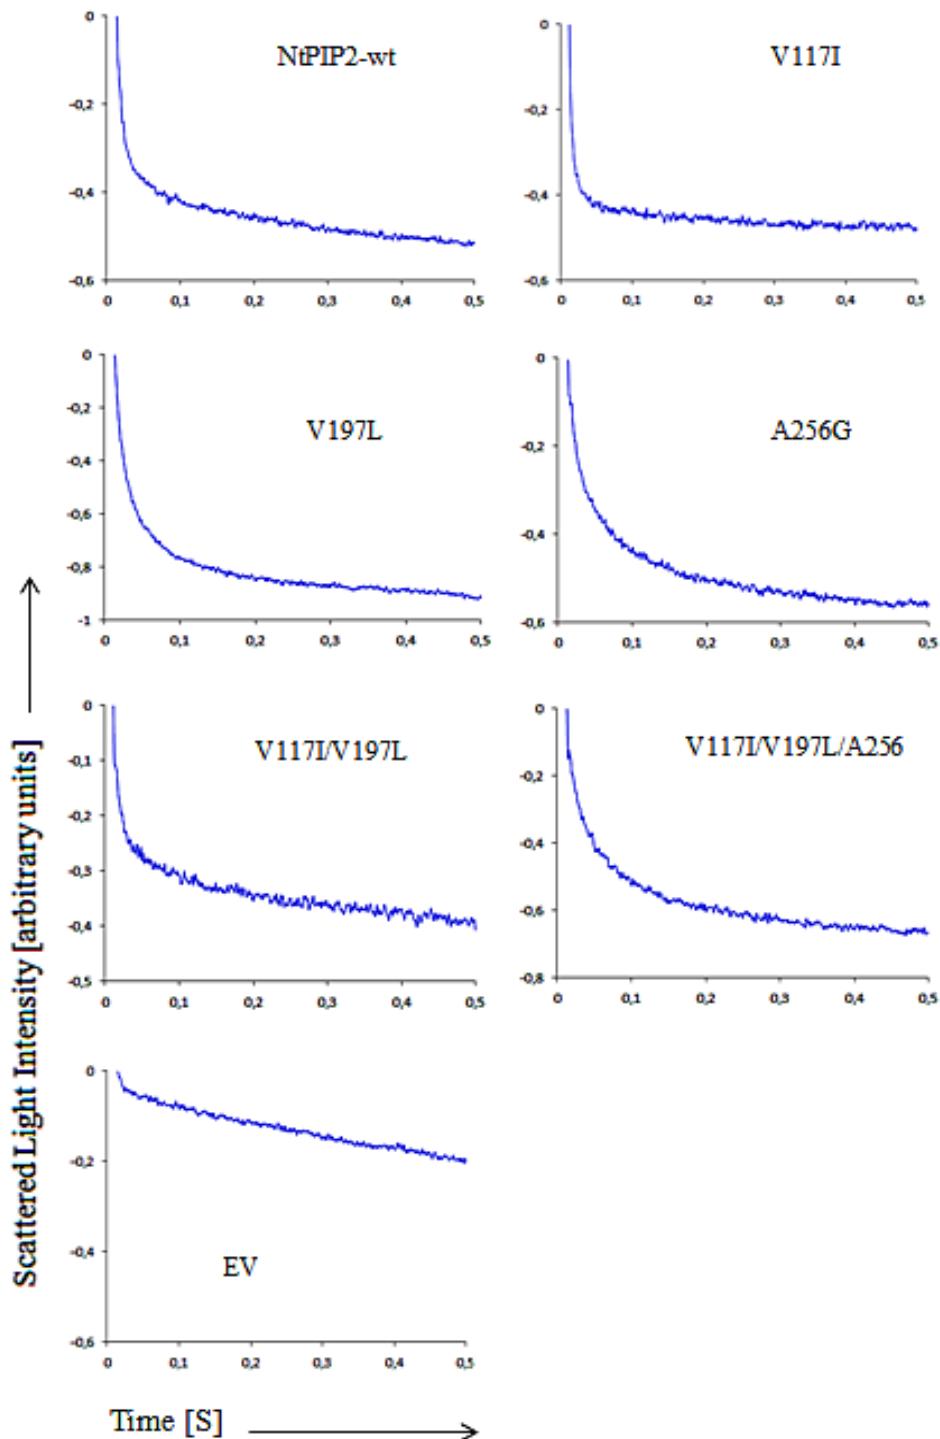

Fig 2.2.3: Water permeability in protoplasts of *Saccharomyces cerevisiae* yeast cells. The figure presents time courses of changes in scattered light intensity in NtPIP2 and its mutants after subjecting the yeast cells to a hypoosmotic shock of 300 mosmol. The raw traces are presented without normalization. Each time course is the average of 20-40 kinetics obtained from 3 individual experiments. The total number of traces acquired for each of the construct was at least 50. Note different scales along the y-axis.

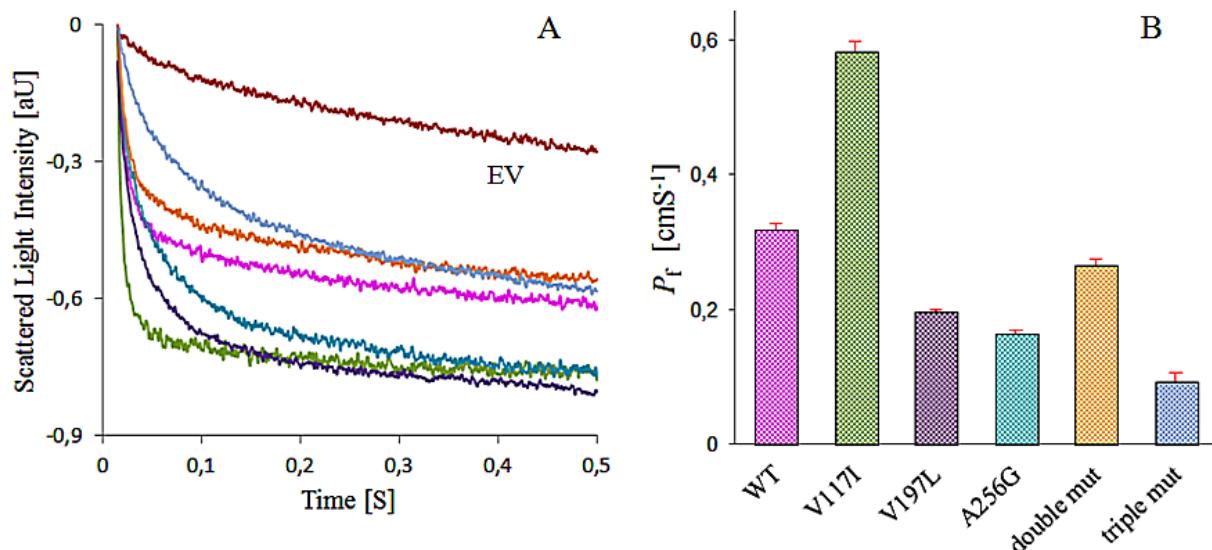

Fig 2.2.4: Water permeability in protoplasts of *Saccharomyces cerevisiae* yeast cells. (A) Time courses of changes in scattered light intensity in NtPIP2 and its mutants after subjecting the yeast cells to a hypoosmotic shock of 300 mosmol. All the traces are presented after normalization. Each time course is the average of 20-40 kinetics obtained from 3 individual experiments. The total number of traces acquired for each of the constructs was at least 50. (B) Osmotic permeability coefficients (P_f) are presented as a bar chart for comparison among various mutants. Error bars represent standard error of the mean. WT = wild type NtPIP2;1, double mut = V117I/V197L, triple mut = V117I/V197L/A256G, EV = empty vector. The color scheme in panel A corresponds to the respective bars in panel B.

2.2.2.2 Homology modeling and interpretation of the results

Homology models were drawn to further understand the significance of the above-mentioned residues in water permeability of NtPIP2;1. The coordinates for the model were provided by the online tool namely “SWISS-MODEL” which used the crystal structure of the spinach PIP2 as the template (PDB entry # 2B5F).

Position I: Position I is located in loop B and there is a possibility that the mutation resulted in a displacement of this loop in a way that physical properties of the pore were changed. This position is located close to an aromatic amino acid Phe112 (belonging to TM3) as indicated by the homology model of the protein structure (Fig 2.2.5). As the residue volume of Ile (166.7 Å) is larger as compared to that of Val (140 Å), the distance between Ile117 and Phe112 might have decreased. The homology model indicates that Ile117 is located almost at a van der Waals distance (4.0 Å) from Phe112 (Fig 2.2.5C). The thrust imposed by the presence of a bigger residue close to this Phe may have tilted it towards the pore. Despite the non-reactive side chain of His, cation-π interaction between the aromatic ring of the Phe-112 and water molecules may have resulted into an intense polar contact.

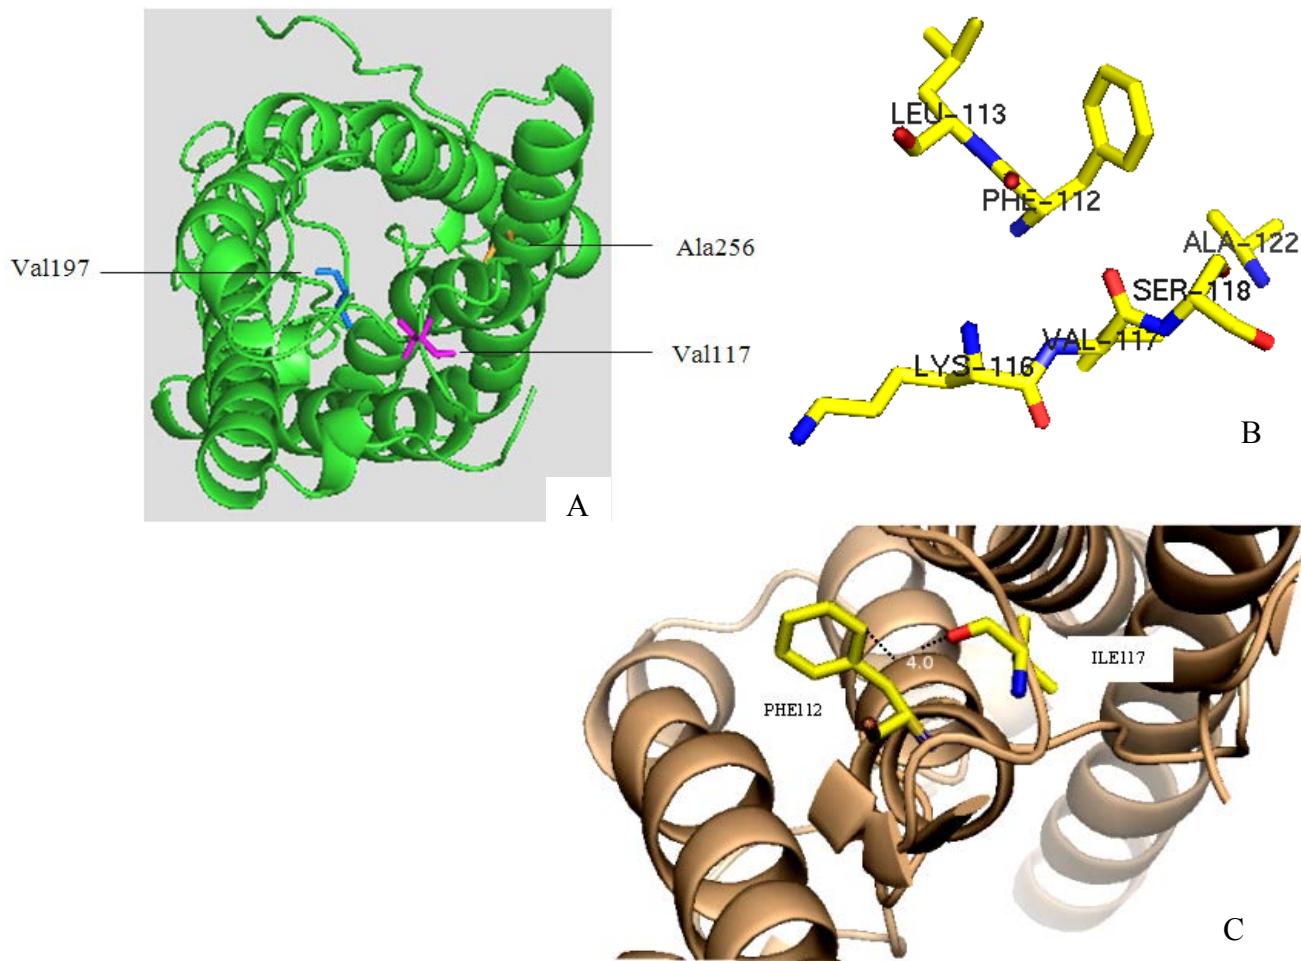

Fig 2.2.5: Homology models of NtPIP2 with the residues of interest shown as a ribbon and stick representation. (A) A cytoplasmic view of the 3 candidate positions focused in the present study. (B) The environment around position I is highlighted in a figure showing Ca^α backbones and the side chains of various amino acids. (C) A cytoplasmic view of a portion of the PIP2 monomer depicting Val117 (position I) and Phe 112 which are located (almost) at van der Waals distance. The coordinates provided by the online tool “SWISS-MODEL” were used to draw the model in the software PYMOL. SWISS-MODEL used SoPIP2 crystal structure (PDB entry # 2B5F) as template.

Further, the overall atmosphere around the Val117 is highly hydrophobic. A region with such higher hydrophobicity “should have” inclined towards the inner cavity which is not the case according to homology model (Fig 2.2.5B). This mutation may have resulted in conformational changes, as a consequence of which the pore characteristics could possibly have altered. There is also a possibility that one or more residues of this region may have interacted with the pore-forming or the functionally-important residues. Whatever the case may be, the significance of this region in solute permeability shouldn’t remain unnoticed because of its location in the loop B which contains one of the two completely conserved NPA motifs in the AQPs.

Position II: The homology model shows that position II is located at the pore mouth (Fig 2.2.6A). Further, it is flanked by the highly reactive imidazole ring of His196 and a non-reactive Pro198 (Fig 2.2.6B). The chances are fair that the remarkable decrease in P_f was because of indirect effects of the mutation on the function. This mutation also involves the substitution by a bigger Leu residue. Although both Pro and Leu possess non-reactive side chains in terms of their role in protein function, the presence of a bigger Leu might have influenced the Pro in a way to jolt the loop into the pore mouth resulting in its partial occlusion. Similarly, Leu may have affected the nearby His (and subsequently the water permeability) in case it has any role in function of the channel. The introduction of a bigger amino acid might have pushed His towards a position unfavorable for the function. Either one or both of the above-mentioned effects may have taken place simultaneously to disfavor the conductance of water.

This position is located in loop D, which is highly versatile in its function and its importance has been signified in the literature (for instance, the role of loop D in gating mechanism). It is quite likely that the mutation at position II had caused some conformational changes leading to a decreased osmotic permeability. Törnroth-Horsefield *et al.* (2006) revealed a gating mechanism in SoPIP2 which involves loop D in opening and closing of the pore. In the closed conformation, loop D folds underneath the pore and a conserved Leu197 located in loop D is inserted into a cavity near the entrance of the channel and occludes it. The residue corresponding to the said Leu197 in case of NtPIP2 is Leu200. Although there is no supporting evidence available, position II may directly interact with Leu200 (Fig 2.2.6B).

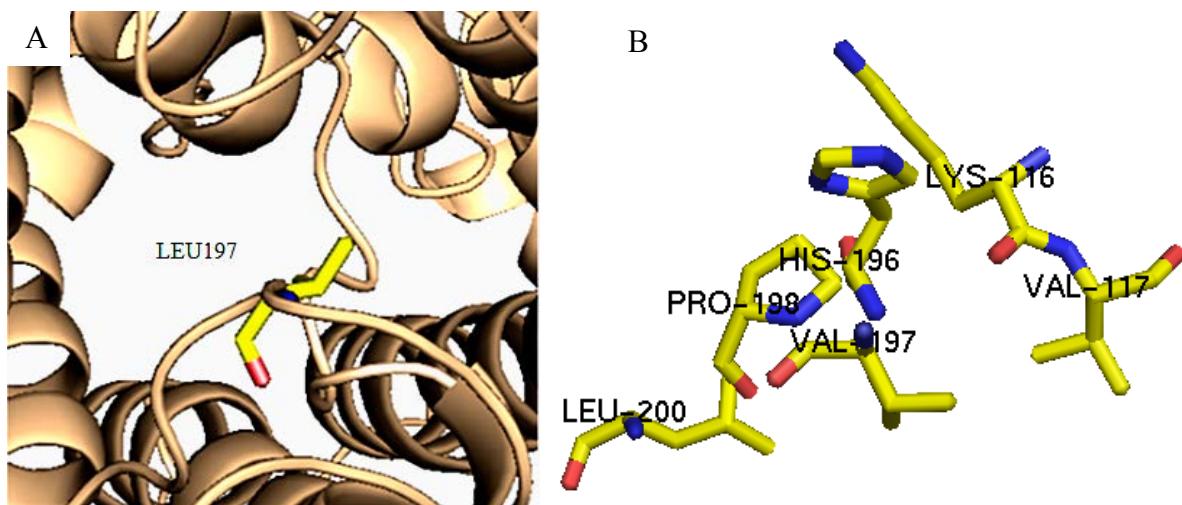

Fig 2.2.6: Homology models to show the environment of position II in NtPIP2. (A) A cytoplasmic view of the water pore shown as ribbon and stick representation, Leu197 can be

seen protruding into the pore mouth. (**B**) The residues around Val197 are highlighted in a figure showing C α backbones and the side chains of various amino acids. The environment around Val197 is quite versatile. Leu200 which is the residue corresponding to Leu197 (important for gating SoPIP2) is also shown. The coordinates provided by the online tool “SWISS-MODEL” were used to draw the model in the software PYMOL. SWISS-MODEL used the SoPIP2 crystal structure (PDB entry # 2B5F) as the template.

Position III: Positions III is located inside the transmembrane helix 6 which is not known to possess any direct role in solute permeability. The significant decrease in P_f (and no gain of ammonia transport function) by substituting Ala with Gly cannot be thoroughly interpreted with the given results. Probably, the introduction of Gly has destabilized the structure or has inflicted some conformational changes in the protein resulting in altered physical properties of the pore (Lin *et al.*, 2006). Either of the above-mentioned situations may reduce the efficiency of the water pore besides keeping the gas pore intact. Apart from the literature, the homology model (Fig 2.2.7) also suggests that this residue itself may not be directly involved in water permeation as the corresponding position is located away from the pore. It is, however, to be noticed that this position lies in a highly hydrophobic atmosphere and is flanked by Ala 259, 260, Pro252 and Phe253. Further, introduction of Gly is known to be even more deleterious for the protein structure (breakage for instance) if its location is inside an α -helix (Kasahara *et al.*, 2007).

It is interesting to note that in PIP2, P_f was decreased by substituting Ala whereas in TIP, P_f was increased by introducing Ala. This indicated some role of Ala at this position in facilitating water permeability. It is tempting to speculate that a non-reactive residue at this position is required which is larger in size compared to Gly (Ala has residue volume of 88.6 Å whereas Gly has 60.1 Å). The mutation at the same position in TIP however, didn't bring about any changes in P_{NH_3} which may be attributed to the difference of structure between TIPs and PIPs as well as to the permeation of NH₃ through a separate pore.

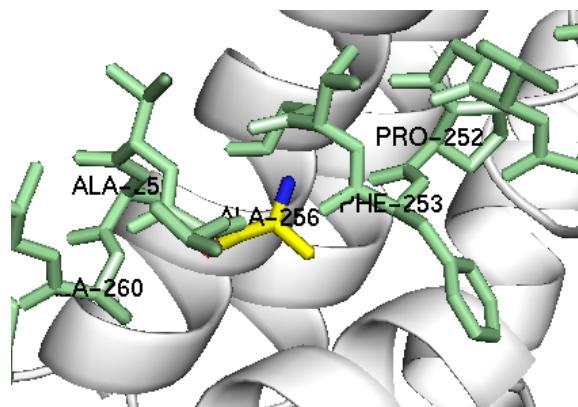

Fig 2.2.7: Position III (Ala256) is located in TM6, a portion of which is modeled as ribbon and stick representation. Ala256 is located in a highly hydrophobic environment and is flanked by Ala 259 and Phe253.

The drastic changes in osmotic permeability of NtPIP2 due to mutations seemed quite surprising particularly because the ammonia transport function in PIP2 (which is otherwise ammonia tight) was not induced at all. Positions I and II involve substitutions among Val, Leu and Ile. The direct involvement of these amino acids in the protein function seems less likely because (i) these possess nonreactive aliphatic side chains (ii) the homology model suggests that these amino acids are located far from the pore (Fig 2.2.5, 2.2.7). Exceptionally, however, position II residue Leu197 in PIP2 is protruding into the pore (Fig 2.2.6). It is not immediately clear as to how Ile and Leu, at the positions I and II of NtPIP2 respectively, perform a role in facilitating water permeability. Probably, the longer size of the aliphatic side chain of Ile and the shorter chain of Val at positions I and II, respectively, are required to maintain the protein conformation (Kasahara *et al.*, 2004). In case of TIP, substitution of Ile rather enhanced osmotic permeability. The data regarding position III revealed that the presence of an Ala at this location is required for effective transport of water through the pore. Interestingly however, the presence of either Ala or a Gly had no role in ammonia conductance.

2.2.3 Molecular signatures of selectivity in TaTIP2;2

2.2.3.1 Mutational analysis

This analysis involved three single point mutations as suggested by the sequence alignment i.e. Ile97Leu, Leu168Val and Gly224Ala. Further, a double mutant (Ile97Leu/Leu168Val) and a triple mutant was also generated that substituted native Ile97, Leu168, Gly224 with Leu, Val and Ala, respectively.

The ability to conduct water and ammonia was studied for all the above-mentioned single, double and triple mutants. The time courses of ammonia permeability are presented in Fig 2.2.8 and Fig 2.2.9A, whereas a bar chart showing the comparison of the permeability coefficients among all the mutants is presented in Fig 2.2.9B. The results revealed that none of the single amino acid mutation had any effect on the function of TaTIP2;2 regarding ammonia permeability and all the mutants behaved similar to the wild type TIP (Fig 2.2.9). A slight increase in P_{NH_3} in case of the position II mutant may be due to an experimental artifact. The double mutant was also not an exception. However, the triple mutant where all the native Ile, Leu and Gly were substituted by (respectively) Leu, Val and Ala was 16 % slower than the wild type. The data analysis suggested that there was little variation among the rate constants of individual kinetics of the triple mutant as indicated by low standard error of the mean. The uniformity among the data may indicate that the mutations didn't inflict instability in the protein however, it is not immediately clear if the altered P_{NH_3} was indeed intrinsic to the mutations. See Appendix 1E for a detailed comparison of P_{NH_3} values among all the TIP variants.

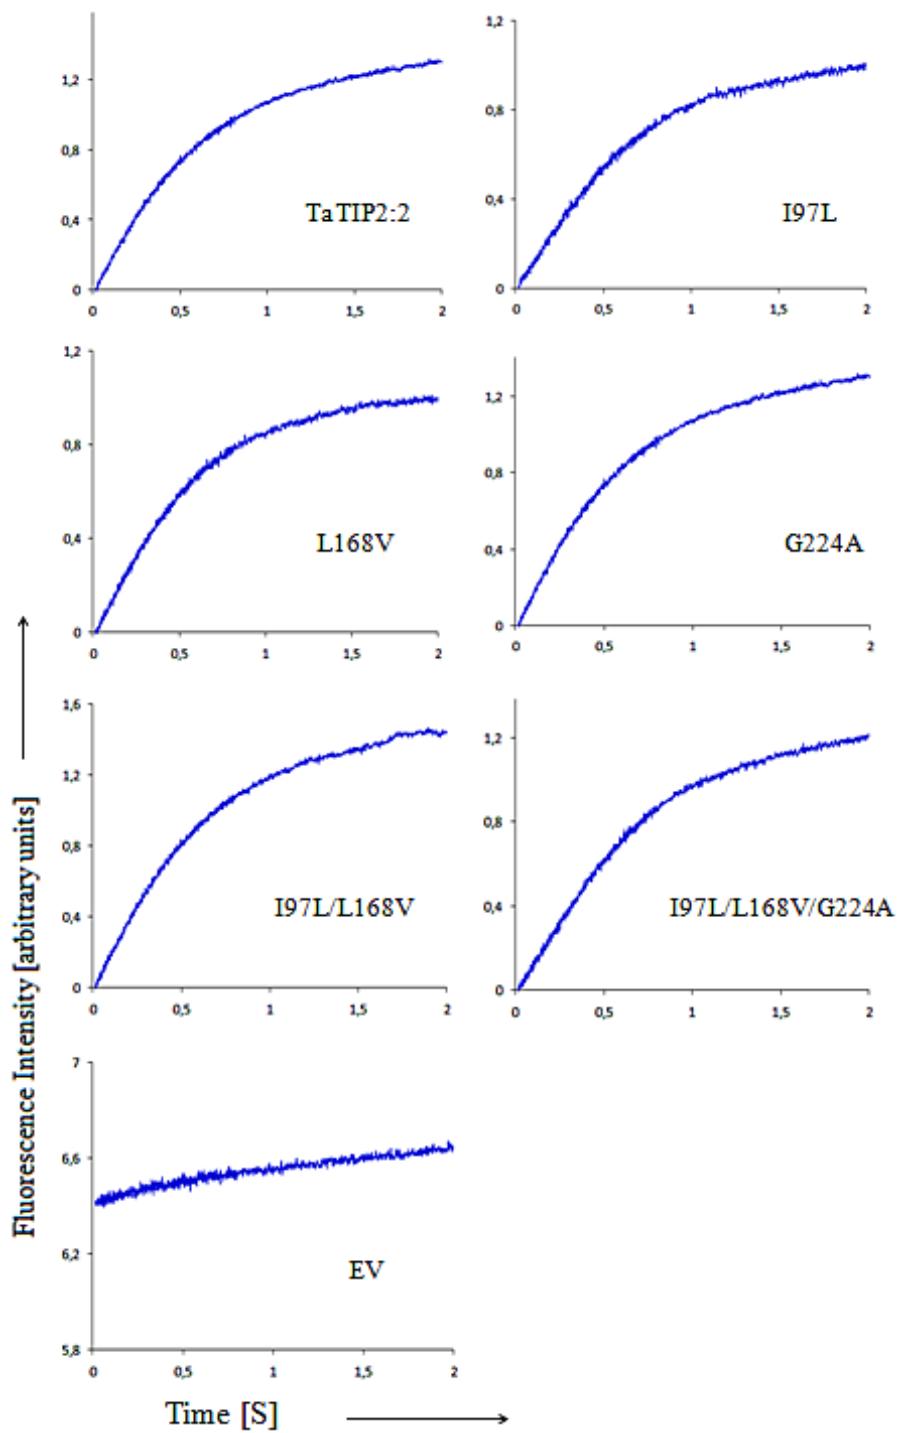

Fig 2.2.8: Ammonia permeability in *Saccharomyces cerevisiae* yeast cells. The figure contains time courses of changes in fluorescence intensity in TaTIP2:2 and its mutants after subjecting the yeast cells to an outer solution containing 25mM NH₄Cl. The raw time courses are presented without normalization. Each time course is the average of 20-40 kinetics obtained from 3 individual experiments. The total number of traces acquired for each of the construct was at least 50. Note different scales along the y-axis.

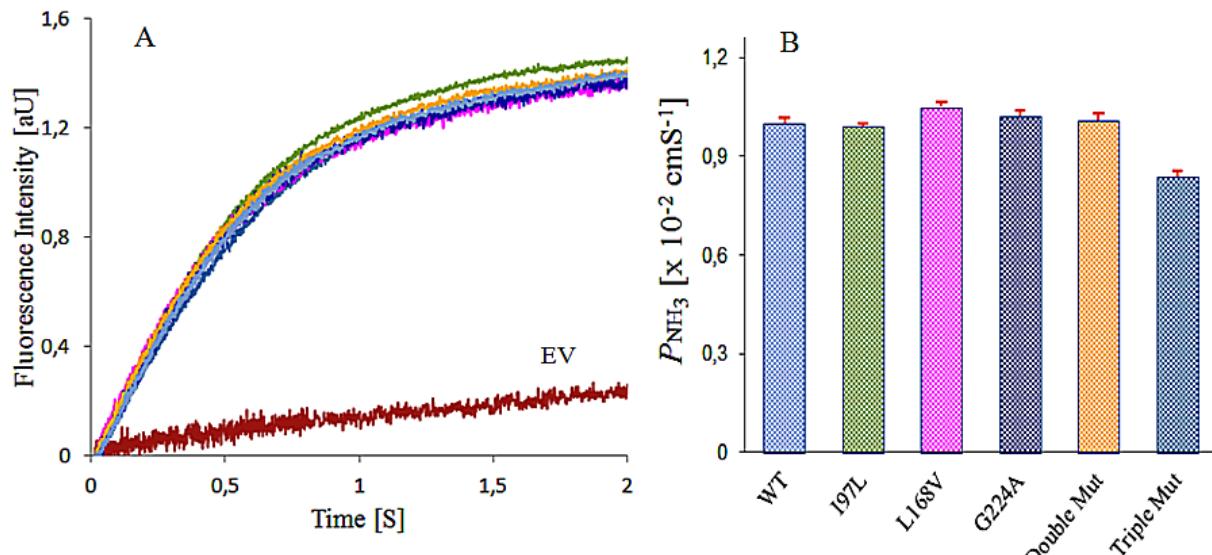

Fig 2.2.9: Ammonia permeability in various mutants of TaTIP2;2. **(A)** The time courses represent changes in fluorescence intensity due to rise in pH after subjecting the *Saccharomyces* cells loaded with Fluorescein to an outer solution containing 25mM NH₄Cl. Each time course is the average of 20-40 kinetics obtained from 3 individual experiments. The total number of traces acquired for each of the construct was at least 50. **(B)** Coefficients of ammonia permeability are presented in bar chart for comparison among various constructs. Error bars represent standard error of the mean. Double Mut = I97L/L168V, Triple Mut = I97L/L168V/G224A, EV = empty vector. The color scheme in panel A corresponds to the respective bars in panel B.

All above-mentioned single, double and triple mutants were also studied for their ability to conduct water. The raw time courses (without normalization) of osmotic permeability for all the constructs are presented in Fig 2.2.10. The functional studies revealed that all the three single mutations were slightly faster in their ability to transport water as compared to wild type TIP (Fig 2.2.11). The double mutant, where the native Ile and Leu were substituted with Leu and Val, respectively, exhibited a significant decrease (24%) in the P_f compared to the wild type. The triple mutant which included additional substitution of Gly by Ala was 18 % slower than the wild type. See Appendix 1D for detailed P_f values comparison among the TIP variants.

Despite varying effects of the mutations on permeabilities in TIP, data of both P_f and P_{NH_3} can be reconciled considering position II and the triple mutants. Both water and ammonia permeabilities were increased (to 5%) in case of position II, whereas the permeabilities were decreased (14-16%) in case of triple mutant.

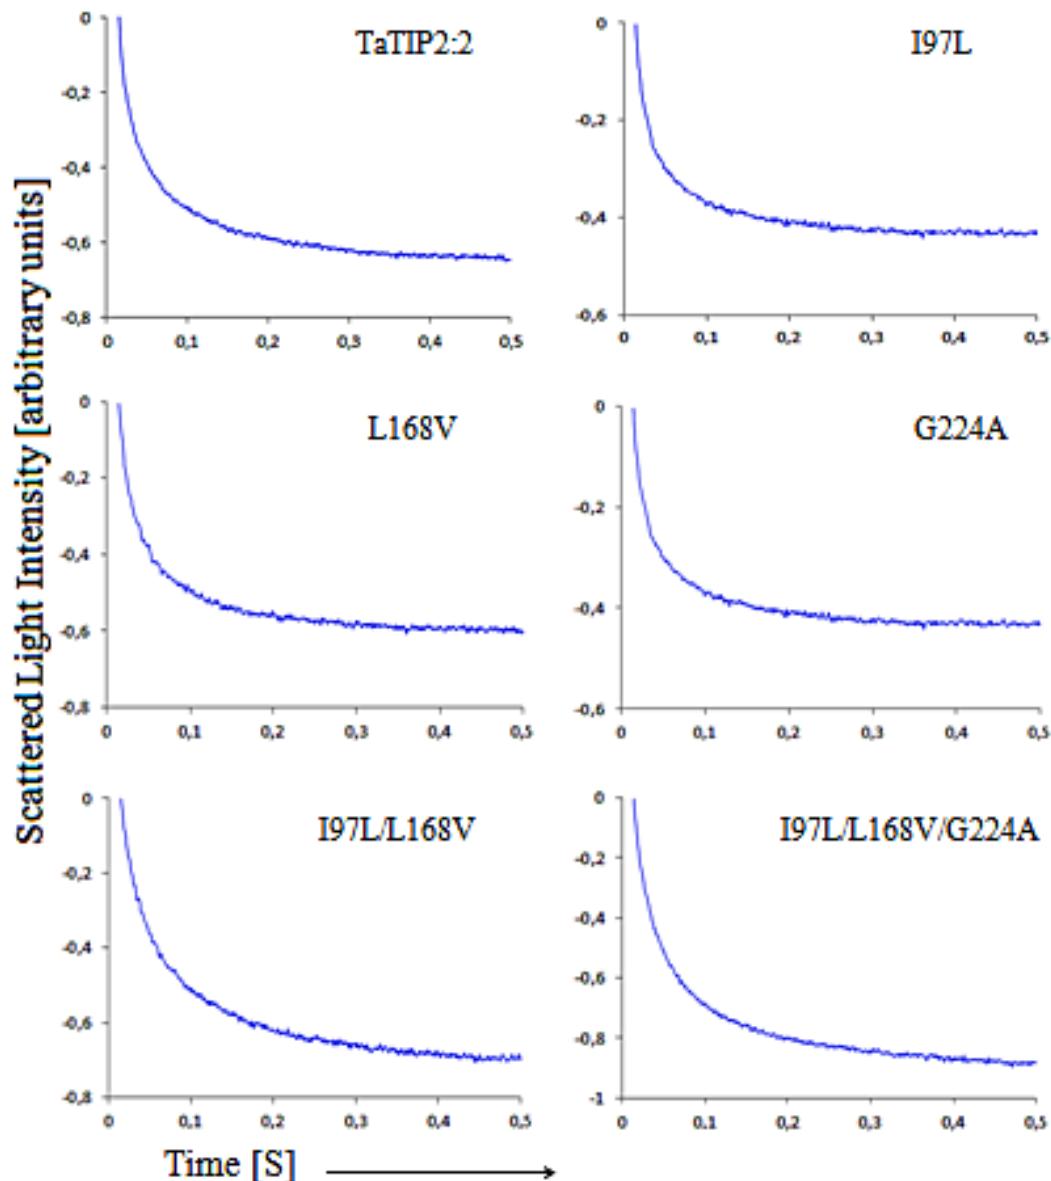

Fig 2.2.10: Water permeability in protoplasts of *Saccharomyces cerevisiae* yeast cells. The figure presents time courses of changes in scattered light intensity in TaTIP2;2 and its mutants after subjecting the yeast cells to a hypoosmotic shock of 300 mosmol. The raw traces are presented without normalization. Each time course is the average of 20-40 kinetics obtained from 3 individual experiments. The total number of traces acquired for each of the construct was at least 50. Note different scales along the y-axis. The time course for the empty vector can be found elsewhere.

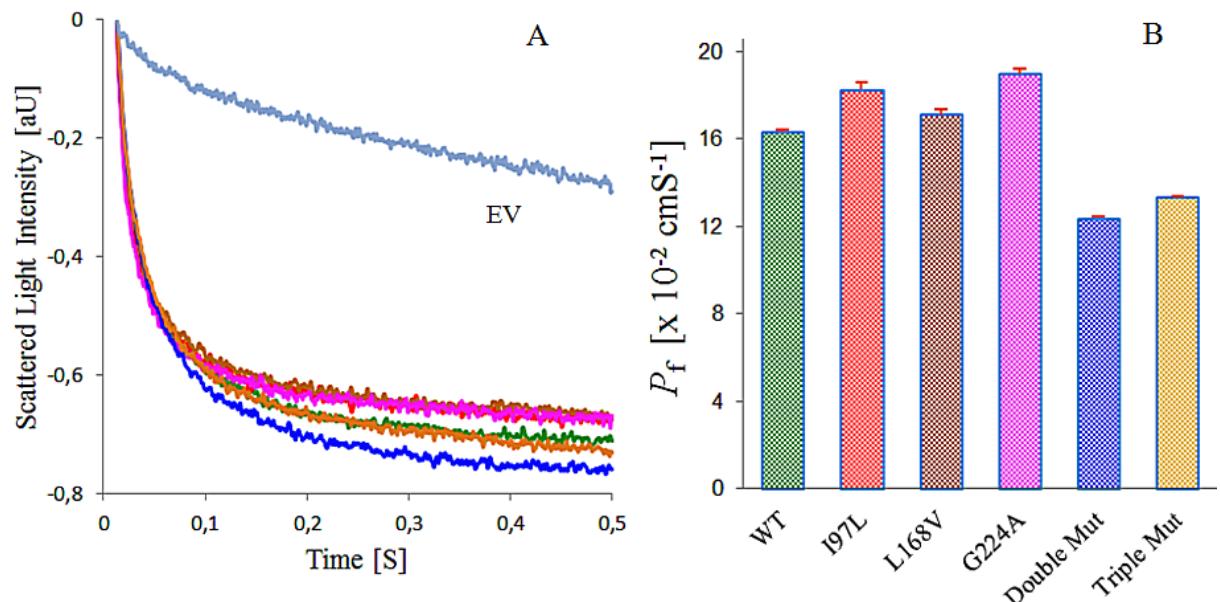

Fig 2.2.11: Water permeability in the protoplasts of *Saccharomyces*. (A) Time courses of changes in scattered light intensity in TaTIP2;2 and its mutants after subjecting the yeast cells to a hypoosmotic shock of 300 mosmol. All the kinetics are presented after normalization. Each time course is the average of 20-40 kinetics obtained from 3 individual experiments. The total number of traces acquired for each of the construct was at least 50. (B) Osmotic permeability coefficients (P_f) of various mutants are presented in bar chart for comparison among the constructs. Error bars represent standard error of the mean. WT = wild type TaTIP2;2, Double Mut = I97L/L168V, Triple Mut = I97L/L168V/G224A, EV = empty vector. The color scheme in panel A corresponds to the respective bars in panel B.

2.2.3.2 Interpretation of the results

The above-mentioned experiment exhibited a similar decrease in P_f in case of both double and triple mutants, indicating no role of Gly in the function of TaTIP2;2. In comparison to the triple mutant, the double mutant is the one which doesn't involve substitution of Gly. The hypothesis is further supported by the fact that a single Gly to Ala mutation exhibited no effect on P_{NH_3} . The identical variations in P_f and P_{NH_3} in the mutations in position II and the triple mutant might be owing to different protein abundance, however, the present study is too restricted to shed light on this fact. There is readily no concrete interpretation available for the change in osmotic water permeability in case of the mutated positions I and III. Probably, they play some structural role as none of them seems to be accessible to the pore. Once again, the varying effect of the residues on water and ammonia permeability may be attributed to a separate gas pore in AQPs.

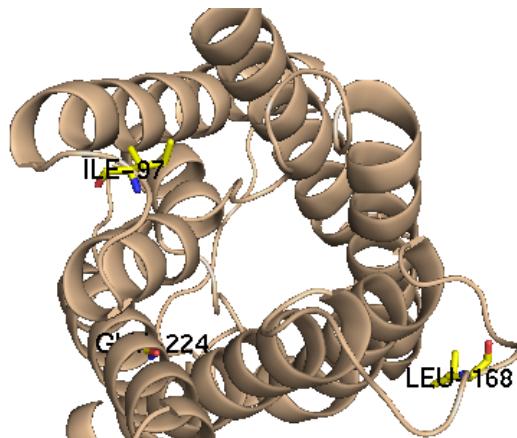

Fig 2.2.12: A cytoplasmic view of the 3 candidate positions in TaTIP2;2 focused in the present study in a ribbon and stick representation.

As it was the Gly to Ala mutation (in triple mutant) which brought about the decrease in P_{NH_3} , it is proposed that Gly (although only in combination with Ile and Leu and not a solo effect) had a role in stability of the structure and the decrease in function was caused by the altered physical properties of the gas pore. Human AQP1, AQP8 and tobacco TIPa also contain a Gly residue at the homologous position (Fig 2.2.1) which signifies its importance in AQPs. Future studies need to be carried out to determine how Gly contributes to ammonia transport facilitation; one approach being mutational analysis in Gly-containing AQPs.

The residues involved in mutational analysis in case of TIP are located far from the pore and the side chains of the concerned residues would be unable to coordinate with the permeating water (according to the homology model in Fig 2.2.12). The Position II, however, is located in the thoroughly investigated loop D. This loop is involved in gating of the aquaporins, including SoPIP2 (Törnroth-Horsefield *et al.*, 2006), AQP0 (Nemeth-Cahalan and Hall, 2000) and AQP4 (Zelenina *et al.*, 2002). Further the intracellular loop D was reported to be involved in pH sensitivity of PIP2;2 (Tournaire-Roux *et al.*, 2003, Fischer and Kaldenhoff, 2008) and AQP3 (Zelenina *et al.*, 2003).

2.2.4 General Discussion

Although, the amino acids focused in the present study are not completely conserved throughout a particular category of AQPs (either water or ammonia conducting), their wide occurrence indicates some role in defining the channel properties.

The mutations are located in loop B (Position I), loop D (Position II) and transmembrane helix 6 (Position III), respectively. Both loops are vital for the

function and structural stability in the family of aquaporins. Loop B contains one of the two highly conserved NPA motifs and mutations in this region critically affect the pore function. Also the cysteine residues introduced in this loop usually take the same role as the highly conserved Cys located in loop E (for instance Cys189 in AQP1) of mercury sensitive AQPs (Shi and Verkman, 1996, Jung *et al.*, 1994b). The loops B and E were proposed to be confronting each other inside the pore in a so-called “hour glass model” (Jung *et al.*, 1994b) and were later verified, through the crystal structure, as the regions containing NPA motifs and taking part in the formation of the water pore (Murata *et al.*, 2000).

The residues focused in the present study may inflict only indirect effects on water permeability due to the afore-mentioned reasons. This assumption is supported by a converse mutation (Ile-to-Val) in RsPIP1;3 which increased its transport activity more than 2-fold (Suga and Maeshima, 2004). This mutation was, however, located at a critical region that is close to the second NPA motif. A Val to Ala mutation in TM2 resulted in a drastic reduction of P_f in rice PIPs. The substitution of native Val caused a change in orientation because of indirect effects on constituents of the selectivity filter, ultimately resulting in unfavorable physical changes in the pore (Zhang *et al.*, 2010).

Unfortunately, the level of protein expression could not be determined in the present study as an appropriate antibody against the TIP was not available. It was attempted in the present study to produce a monoclonal antibody, but it didn't show any affinity (data not shown). The results have been interpreted, assuming that the protein abundance was the same in all mutants, although this might vary in different mutants after normalizing the P_f data against the protein abundance. It should be noted that, in some instances, single point mutations may indirectly affect protein function through an extensive distortion of the protein structure (Kasahara *et al.*, 2006). If proteins are equally abundant in all mutants and the variation in P_f is intrinsic to the mutations, a detailed mutational analysis involving amino acid substitutions of different sizes and secondary structure propensities could further elaborate the significance of said positions in water permeability and mechanism of interaction with the solutes (s). As long as the protein structure is not resolved, other approaches such as cysteine scanning analysis might shed light on access of the concerned residues to the water pore (although less probable).

Besides the mutants focused in the present experiment, some more conserved residues were pointed out in a recent review (Litman *et al.*, 2009). The predominantly water permeable AQPs of mammals, i.e. AQP1, 2, 4, 5, 6 and the plant aquaporin PIP2 have a histidine at position 180 (numbers corresponding

to hAQP1 will be referred to hereafter) and an isoleucine at position 184. The aqua-ammoniaporins, i.e. AQP3, 7, 9, 10 in mammals and TIP2;x in plants have got a glycine at positions 180 and 184. At position 190 (arbitrary position 251 in Fig 2.2.1), the exclusive water conducting AQPs contain Ser or Gly, whereas the ammonia conducting ones mostly contain Ala. Interestingly, TIP contains Ser at this position (see Appendix 2 and Fig 2.2.1).

The molecular signatures distinguishing between water conducting aquaporins and the aqua-ammoniaporins are extended beyond the selectivity regions in AQPs. The water conducting AQPs can be converted into water/ammonia conducting pores and vice versa by point mutations. In case of an aqua-ammoniaporin, if the isoleucine corresponding to position 180 of AQP1 is replaced by a histidine and the glycine at position 189 is replaced by a cysteine, the aqua-ammoniaporin would become an exclusive water channel. Likewise, if an AQP1 mutant is generated, in which the histidine at position 180 is replaced by an alanine, the aquaporin becomes ammonia-permeable (Beitz *et al.*, 2006).

None of our mutations falls even in the domains suggested by Litman *et al.* (2009) as those are mostly located closer to the second NPA motif. The sequence alignment (Fig 2.2.1) revealed an appealing position 197, which is very close to the second NPA motif. At this location, the hydrophobic residues phenylalanine and leucine are almost equally represented in both, exclusive water channels as well as aqua-ammoniaporins. The dominance of merely these two residues in AQP family needs to be investigated keeping in view the difference of isostericity between Phe and Leu that ambiguates the requirement of hydrophobicity at this position.

2.2.5 Conclusions

Keeping in view the (i) conserved nature of these residues and (ii) drastic changes in P_f by these mutations in PIP2, the concerned positions require further investigation. The following inferences were drawn from the results obtained:

- (i) The residues studied in the present experiment didn't appear to play a major role in ammonia selectivity. None of the mutations could induce ammonia permeability in NtPIP2, however, each of the mutations had a strong effect on P_f . Likewise, even the triple mutant in TaTIP2;2 (where all the native residues were substituted with their homologs from NtPIP2), just partially restricted ammonia conductance through the pore. The results provided only little evidence in support of our hypothesis. However, the available experimental data together with the conserved nature (not completely) of these residues lead us to propose their minor role (solo or cumulative

effect) as a part of the selectivity mechanism. A recent study revealed that either of the two essential regions (NPA motif or ar/R region) doesn't suffice alone to impose a selectivity barrier on the potential solutes permeability. It is in fact the cumulative effect of the both as shown by the point mutations in the NPA motif and ar/R region of AQP1 (Wu *et al.*, 2009). Therefore, further mutational analyses should be planned in combination with both selectivity regions.

(ii) Nearly all the amino acid substitutions may render the protein unstable to varying degrees. The stability of a protein can be improved by substituting amino acids for those with increased secondary structure propensities. The aromatic amino acids particularly Trp and Phe, which fall in the middle of the propensities scale, significantly stabilize the residual structure (Finnegan and Bowler, 2010). It is recommended that the native Val, Ile and Leu residues are substituted by those with varying secondary structure propensities, but similar molecular volume and side chain properties. Glu and Thr may be good candidates for future studies. The former should receive particular attention because of its highly reactive side chain and increased propensity. The different effect of mutations on P_f and P_{NH_3} provides a hint in support of the presence of a central pore.

(iii) Unfortunately the protein expression data is missing in this study. Although less likely because of isosteric similarities in the investigated positions, it would be parsimonious to suggest a normalization of the data against the protein abundance.

(iv) The residues reported here are among those which have been suggested in the alignment comparing ammonia permeable AQPs against the ammonia tight ones. It is recommended that further investigations include even more conserved residue that is Phe in case of aqua-ammoniaporins and Leu in case of water specific AQPs (Fig 2.2.1). Their respective positions in case of TaTIP2;2 and NtPIP2 are 201 and 233 (the corresponding position in case of hAQP1 is 197).

2.3 Molecular determinants of selectivity in AQPs: *Investigations on SF regions and structural domains*

The previous chapter included substitution of several potential molecular signatures that didn't seem to play any important role in ammonia selectivity in AQPs. The investigations were broadened to include the selectivity regions and some of the functionally relevant domains of TaTIP2;2 and NtPIP2 in an attempt to understand the nature of the selectivity barrier imposed by the predominant water conducting channels to hinder the ammonia conductance. These studies involved the same ammonia conducting TaTIP2;2 and non-conducting NtPIP2;1 aquaporins.

2.3.1 Molecular signatures of selectivity in selectivity regions

2.3.1.1 Mutational analysis in the ar/R region

The ar/R region of TaTIP2;2 is a tetrad of His64, Iso179, Gly192 and Arg199 residues, whereas that of NtPIP2;1 is comprising of Phe83, His212, Thr221 and Arg227, which are highly conserved among the PIPs. The positions are designated as H2, H5, LE1 and LE2, respectively. The selectivity filter regions of both TIP and PIP were swapped through sequential mutations in order to study the molecular signatures contributing to ammonia selectivity in AQPs. As to the investigations on TaTIP2;2, the following mutants were generated:

- (i) three single mutants, i.e. His64Phe, Ile197His, Gly192Thr
- (ii) a double mutant, i.e. His64Phe/Gly192Thr and
- (iii) a triple mutant, i.e. His64Phe/Ile197His/Gly192Thr in which the ar/R constriction mimics that of NtPIP2.

All the above-mentioned mutants of TIP proved to be nonfunctional for both water and ammonia transport. The raw time courses (without normalization) of ammonia and water permeability are presented in Fig 2.3.1. It was a surprising outcome as the residues substituted do already exist in water selective AQPs and are highly conserved. Unfortunately, the protein expression of these mutants couldn't be determined due to the lack of an appropriate antibody. An important evidence is however available (see the caption 2.3.1.3 on proton leakage), which confirms that the protein was not expressed in case of the mutant H64F.

In case of tobacco PIP2;1, a predominantly water conducting channel, the individual constituents of the ar/R constriction of TaTIP2;2 were also desired to be replaced. Unfortunately, only one residue at the position LE1, that is Phe83, could be

substituted by His. The other two residues His212 and Thr221 couldn't be substituted, because of failure to accomplish the mutagenesis. The mutant F83H didn't show any function; even the pore lost its ability to conduct water (refer to the general figure 2.3.1 for the raw time courses (without normalization). Immunoblot assay confirmed that it was due to nonexpression of the protein (Fig 2.3.9).

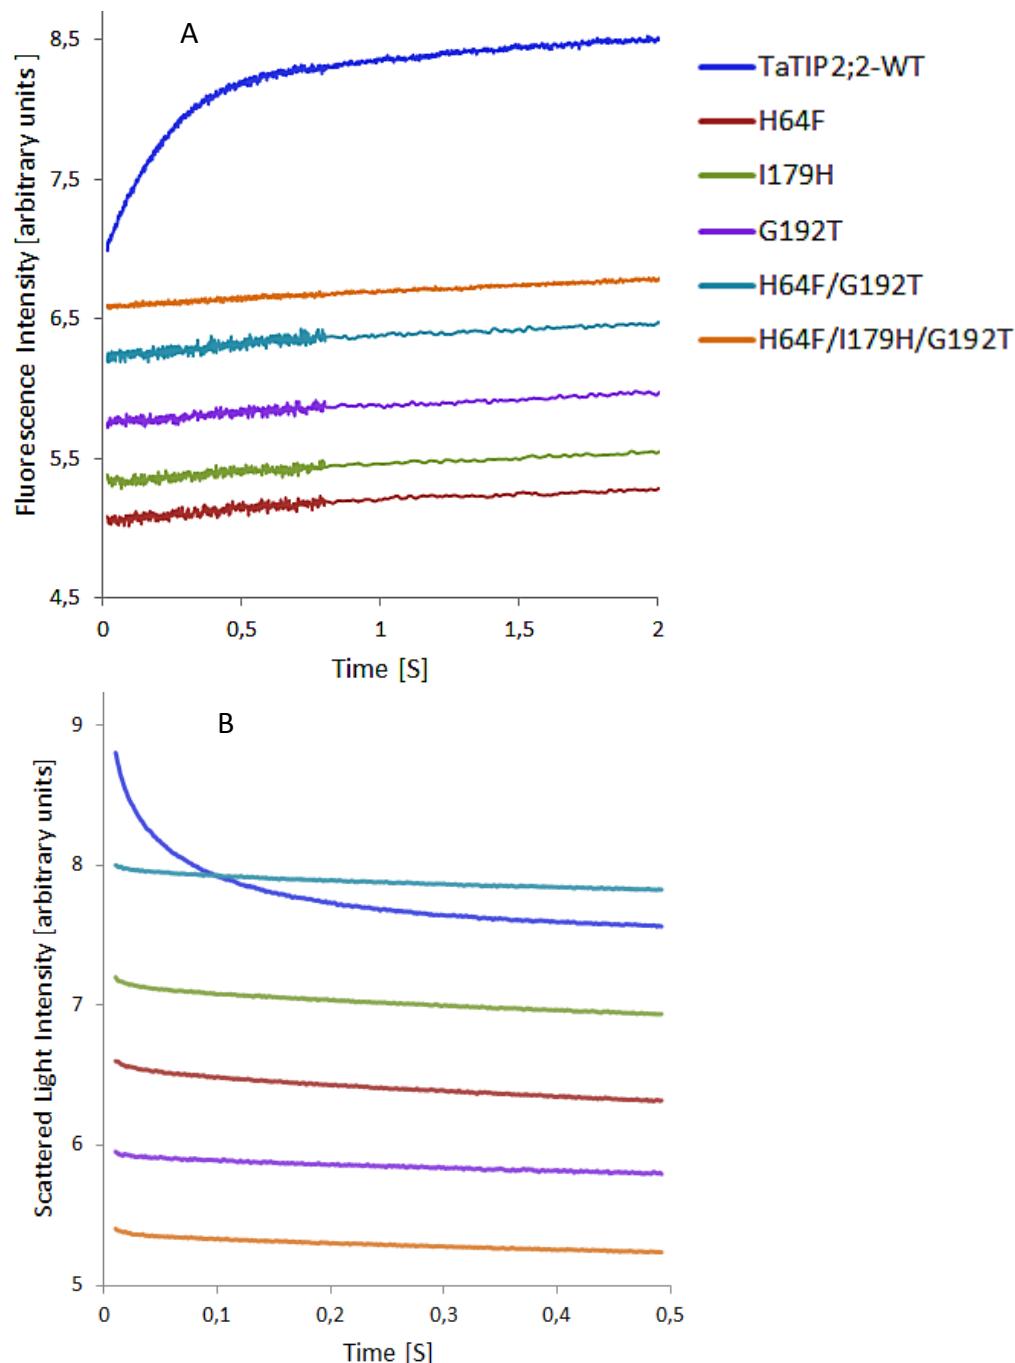

Fig 2.3.1: Ammonia (A) and water (B) permeability in various mutants of TaTIP2;2. The time courses for ammonia permeability represent changes in the fluorescence intensity due to rise in pH after subjecting the *Saccharomyces* cells loaded with Fluorescein to an outer

solution containing 25mM NH₄Cl. The time courses for water permeability represent changes in the scattered light intensity after subjecting the yeast cells to a hypoosmotic shock of 300 mosmol. All the time courses are presented in original (without normalization) due to the reason that the normalization elevates the initial brief but faster component by several orders of magnitude. Each time course is the average of 20-40 kinetics acquired from 3 individual experiments. The total number of traces acquired for each of the construct was 50. Note: These kinetics would serve as representative ones for all the nonfunctional constructs following in this section. The color scheme is same in panels A and B.

The wheat TIP2;1 also contains His, Ile and Gly residues at the (respectively) H2, H5 and LE1 positions. All these residues were indispensable for ammonia transport. However, interestingly, yeast complementation performed in the mutated ar/R region (mimicking that of AQP1) of wheat TIP2;1 indicated that the residues constituting the tetrad do not play a vital role in protein folding or trafficking (Jahn *et al.*, 2004).

The His and the highly conserved Arg were dispensable for water transport, as observed in AQP1, which implies that water permeability in AQP1 is independent of the polarity at the ar/R constriction (Wu *et al.*, 2009). The position H5 of TaTIP2;2 contains a small residue that is Ile, which renders the ar/R region wider in diameter and also makes it more hydrophobic. These are general characteristics of ammonia conducting AQPs (see homology model in figure 2.3.2).

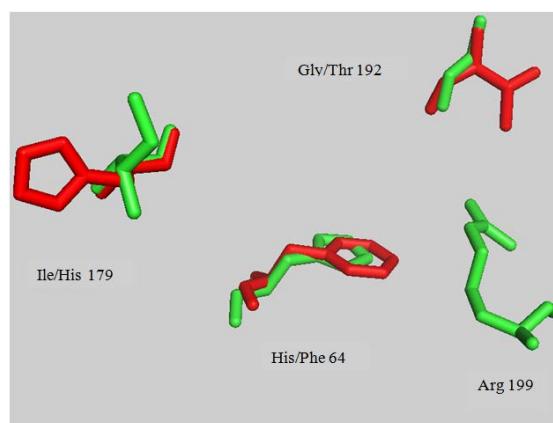

Fig 2.3.2: The residues constituting the ar/R tetrad of TaTIP2;2 derived from the homology model. The native and the mutated residues are superposed on each other and the figure shows their C_α backbones and the side chains to highlight their biochemical properties as well as the effect of mutations on the pore characteristics. The model was drawn in the software PYMOL using the coordinates provided by an online tool SWISS-MODEL. The latter tool used the crystal structure of human AQP4 (PDB entry # 3GD8) as template. Color scheme: native residues are shown in green, mutated residues in red.

In predominant water conducting AQPs, the constriction tetrad is comprised of Phe, His, Cys and Arg. The replacement of native Phe residue (position H2) by a His in MD simulations resulted into blockage of the *Arabidopsis* PIP2 pore (Dynowski *et al.*, 2008). The Cys in most of the water, ammonia and glycerol conducting AQPs is replaced by an aromatic functional group carrying amino acid. In case of aquaamoniaporins, the Cys residue is replaced by very small residues like Gly/Ala (reviewed by Litman *et al.*, 2009). The His at position H5 is critical for water/ammonia transport specificity. If this His is replaced by Ala in predominantly water permeable channels, the channel would gain the function to transport ammonia (Beitz *et al.*, 2006).

The TIP contains the following polar residues in its SF regions: His and Arg (in ar/R region) and Asn (belonging to both NPA motifs). In the ar/R region, the residues Phe and His serve as hydrogen bond donors which could significantly decrease the energetic cost of water transport and hence account for very high intrinsic water transport rates as compared to other AQP isoforms.

2.3.1.2 *Mutational analysis in the NPA region*

In this experiment, the native Asn from each of the NPA motifs was substituted by His and as a result 2 mutants were generated. The mutants were analysed by stopped-flow spectroscopy to study their ability to facilitate water and ammonia transport. The results revealed that both mutants were nonfunctional. Refer to the general figure for raw time courses (without normalization) given earlier in this section section (Fig 2.3.1).

This study involved the substitution of Asn by His in both the motifs as it was decided to introduce an aromatic ring in the water channel keeping in view the close location of both selectivity regions. The presence of an aromatic ring close to the NPA and the ar/R regions was expected to result in changes in solute permeability without affecting the pore integrity. The loss of function was quite surprising, as both Asn and His are polar residues and may serve as hydrogen bond donors in the context of the requirement for water permeation through the pore. However, His has a positively charged imidazole group and is a particularly reactive amino acid. In molecular dynamics studies, Kong and Ma (2001) also suggested substitution by a His residue because of its size and chemical nature being similar to Asn.

Unfortunately the protein expression data is missing due to the lack of an appropriate antibody against the TIP. There are, however, some supportive evidences (see the caption 2.3.1.3 on proton leakage) available, which confirm that the protein was expressed in both mutants.

Probably, the introduction of an aromatic ring (N-to-H mutations in the motif) has tapered down the constriction and has sterically hindered the passage of heavier molecules of water (2.8 Å) and ammonia (2.9 Å). As previously mentioned, the pore at this region doesn't permit any molecular entity larger than 2.8 Å. Selectivity by size also plays a role to exclude the larger solutes from the pore constriction (Walz *et al.*, 2009).

This highly conserved nature of the NPA motifs indicates that each of the residues constituting this motif is inevitable, but the mutational analyses reported so far revealed contrasting effects. Several studies confirmed that the Asn of both NPA motifs are involved in water permeability through H-bonding with water molecules (Sui *et al.*, 2001, Yakata *et al.*, 2007, Horsefield *et al.*, 2008). See a MD simulation (Horsefield *et al.*, 2008) presented in figure 2.3.3 which shows interaction between asparagines of the NPA motifs and the water molecules.

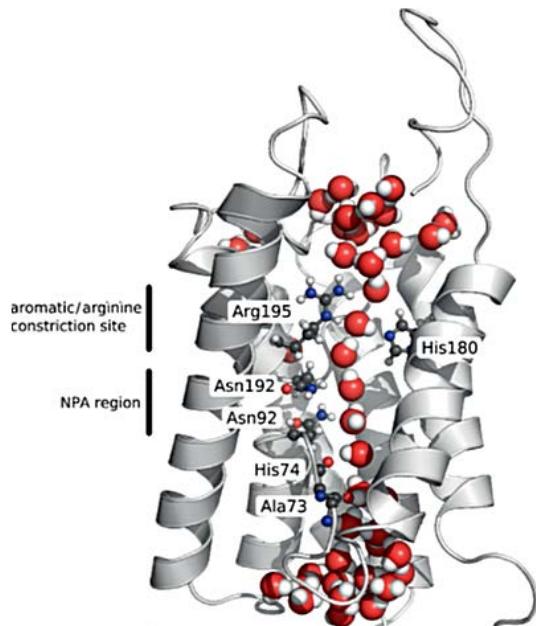

Fig. 2.3.3: Snapshot from an MD simulation of AQP1 showing a single file of water inside the AQP1 channel. Some water-interacting amino acid side chains are shown in ball-and-stick representation. The asparagines of the NPA motifs form strong hydrogen bonds with permeating water molecules (shown as red spheres). Another constriction ar/R region is located at the extracellular exit of channel. (Adopted from Horsefield *et al.*, 2008)

The NPA motifs of AQP11 and AQP12 are exceptionally different in the entire family of AQPs. The loop B motif is NPC in AQP11 (Yakata *et al.*, 2007) and NPT in AQP12 (Itoh *et al.*, 2005). The NPC motif is essentially required for full protein expression, as the exchange of the Cys by an Ala almost abolished water permeability (Ikeda *et al.*, 2010). The water permeability in PfAQP (a parasitic

aquaglyceroporin) is even higher than that of orthodox AQPs. It contains NLA and NPS instead of NPA motifs in (respectively) loop B and loop E, but the structural basis for the much higher water permeability or the selectivity mechanism is not provided by the unusual motifs (Hansen *et al.*, 2002). Fps1, a glycerol facilitator of yeast and a close homologue of the aquaglyceroporins Glpf, also contains varying motifs that is NPS and NLA in its loops B and E, respectively (Bill *et al.*, 2001).

No deletion of NPA motifs in plant AQPs has been reported so far. Deletion of one or both motifs in mammalian AQP4 impaired trafficking, indicating that the NPA motifs play an important role in the plasma membrane expression (Guan *et al.*, 2010). The deletion of even both NPA motifs had a little effect on the osmotic permeability and it didn't influence the expression and the intracellular processing of AQP1 at all (Jiang and Ma, 2006). A simulation study in AQP1 indicated that the substitution of native proline of the motif by Leu doesn't affect overall hydrophobicity of the channel. The presence of Leu had a far-reaching effect, but these were compensated by the covalent changes taking place throughout the protein (Newby *et al.*, 2008).

Replacing Asn for Asp in the NPA region enabled a low proton permeability in AQP1, but the proton leakage was remarkably higher when the His and the Arg belonging to the ar/R were substituted by Ala and Val, respectively (Wu *et al.*, 2009). Some other reports also indicate that a major electrostatic barrier against the transport of solutes originates from the ar/R region in comparison to the NPA motif (Chen *et al.*, 2006, Beitz *et al.*, 2006). The residues in the NPA region and the helix dipole are not solely responsible for imparting selectivity to the AQPs (Kato *et al.*, 2006).

2.3.1.3 Proton leakage through SF variants of *TaTIP2;2*

This section has described the functional analyses of a number of mutations in the NPA motifs as well as in the ar/R region. All the mutants proved to be nonfunctional and the protein expression in case of the TIP variants couldn't be determined due to the lack of antibody. Therefore, it was decided to confirm the presence of the protein by employing some indirect approach. It was considered most realistic to study the leakage of protons, as any of such mutations is expected to cause changes in the chemical or geometric properties of the selective channel (and less likely breakage of the pore).

Ammonia exists in nature in two forms, the slightly basic NH₃ and the acidic NH₄⁺ form. The more acidic the pH, the more is the chemical equilibrium shifted towards the charged form of ammonia, which is ammonium. The Mep family comprises of

the high-affinity ammonium transporters, which act independent of the prevailing pH. According to the Henderson–Hasselbalch equation, almost 80% of the ammonia is available/transported in the form of NH₄⁺ at pH of 5.2.

$$\text{pH} = \text{pK}_a + \log \frac{[\text{A}^-]}{[\text{HA}]} \quad \text{----- Equation (IIIa)}$$

The data obtained from the given experiment must not be compared with those presented in the section I (concerning to ammonia permeability in the TIP mutants) of this chapter. The reasons are: (i) the pH used in the previous experiments was 8.0 which is different to the one employed in the experiment on proton leakage. (ii) The buffer used in the previous experiments was Tris/HCl whereas it was malate in the present one. In the present experiment, the pH had been varied in the range from 5.2 to 7.2.

This study involved both the afore-mentioned mutations in the NPA region (N84H and N196H) as well as a mutation selected at random from the ar/R region (that is H64F). The results revealed, that the mutations in the NPA motifs, where native Asn was substituted by His had allowed some leakage of protons (Fig 2.3.4). However, the mutation in the ar/R region (H64F) remained non-conducting to the protons (refer to general Fig 2.3.1). The results are presented only as normalized time courses (Fig 2.3.4) and the precise coefficients of proton permeability were not calculated. It is generally believed that the aquaporins conduct ammonia essentially in the form of NH₃ and they don't permit the charged form of ammonia (Holm *et al.*, 2005, Saparov *et al.*, 2007). It is noteworthy that the function observed in the NPA motifs might be owing to the leakage of some other solute(s). Although this phenomenon was not further investigated, we tempt to speculate that it is probably nothing else but the conductance of the protons.

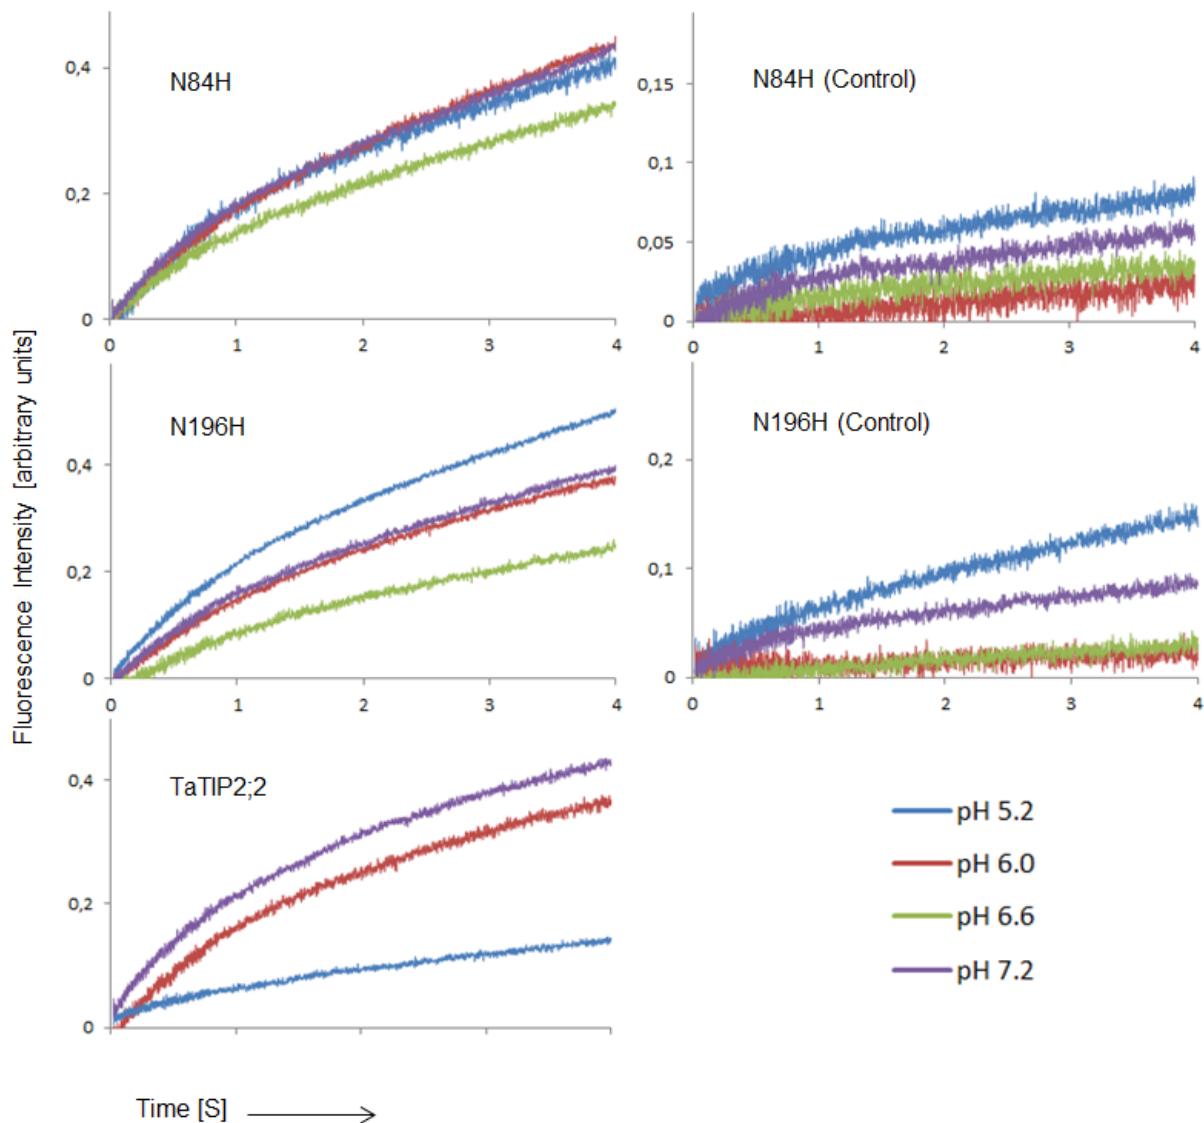

Fig 2.3.4: The presence of varying ammonia species under different pH has been exploited in determining H^+ leakage. The time courses for the leakage of H^+ as indicated by the change in the fluorescence intensity are presented in this figure. The pH of the outer solution containing NH_4Cl was varied from 5.2 to 7.2. Control panels stand for the measurements involving the mutants in which the protein expression was not induced. Each curve is the average of at least 30 traces belonging to 3 independent experiments. The total number of traces acquired for each of the construct was at least 50. Note the different scales along Y-axis. The color scheme is same in all graphs.

Both mutants of the NPA motifs proved to be functional in this experiment unlike their nonfunctionality in the prior studies regarding water and ammonia permeability. The possible explanations might be: (i) The experiments on ammonia were conducted at a pH of 8.0, but the proton permeation was studied in a pH ranging from 5.2 to 7.2. (ii) The buffer used in the proton permeation experiments was maleic acid and the one used for studying water and ammonia permeation was

Tris/HCl. (iii) The fact that the mutation in the ar/R region (H64F) didn't exhibit any proton conductance, further authenticates the present experiment on protons. The results indicate that the loss of ammonia and water transport function in all the previous experiments was intrinsic to the mutations and not because of the non-expression of the protein.

In contrast to the case of the NPA mutants, the mutation in the ar/R region (H64F) exhibited no proton leakage, even at pH 5.2. The kinetics for these mutants are not presented here because of their similarity to other nonfunctional mutants (refer to general figure 2.3.1).

In the present experiment, the conductance of some other cations (and not the protons) can't be ruled out, because of the following reasons: (i) in case of N84H, at pH 7.2, the proton permeability was quite comparable to what was observed at pH 5.2. (ii) In both mutants, the proton leakage is higher at pH 7.2 than at pH 6.6. Unfortunately, these discrepancies can't be reasoned, as comprehensive investigation of this issue is lacking. Once again, the primary objective of this experiment was to determine the protein expression and not to investigate the ability of TaTIP2;2 to facilitate passage of either protons or a solute, other than water/ammonia.

The proton is the smallest and the most mobile cation in aqueous solutions, yet it can't permeate through the selectivity regions of aquaporins. The permeability of solutes in AQPs is determined just partially by the size-restrictive mechanism and the pore size is not the only selectivity barrier against the solute transport (Phongphanphanee *et al.*, 2010, Hub and de Groot, 2008, Wang *et al.*, 2005). The glycerol facilitator GlpF has the widest pore of 3.3Å diameter (Fu *et al.*, 2000), whereas a predominantly water conducting channels like PIP2 have the smallest, that is 2.1Å (Törnroth-Horsefield *et al.*, 2006) and the AQP1 has a pore diameter of 2.8Å (Murata *et al.*, 2000).

The role of the selectivity regions is not yet fully understood. The electrostatic repulsion generated by the positive charge of Arg in the ar/R region, as well as the size-imposed restriction excludes various ions and protons to permeate (reviewed by Hub *et al.*, 2009). Both, the ar/R region as well as the NPA motif hinder the leakage of protons, however the former controls proton exclusion more tightly than the NPA motif (Chen *et al.*, 2006, Wu *et al.*, 2009).

The Asn of the NPA motif caps the positively charged ends of two short α -helices and a high electrostatic barrier restricts proton leakage through the pore (Li *et al.*, 2011, Chakrabarti *et al.*, 2004). In contrast, the NPA region prevents more effectively leakage of Na^+ compared to protons. The AQP1 mutants, in which a positive charge in the constriction was removed and the pore was widened by

substituting Arg with Val or His with Ala, exhibited some proton leakage (Beitz *et al.*, 2006). The exchange of asparagine for aspartate in the NPA region enabled low proton permeability (Wu *et al.*, 2009).

2.3.2 Domain swapping

2.3.2.1 *Swapping TM helices & connecting loops between TIP and PIP*

The studies were further broadened to determine the molecular signatures responsible for imposing the selectivity barrier to block the ammonia permeation in predominantly water conducting channels (NtPIP2 in our case). Various domains were focused in this experiment; the loops A, D and the transmembrane helices 2, 5 were swapped between TaTIP2;2 and NtPIP2;1 under different arrangements as given in the figure 2.3.5. In the tetrameric view of aquaporins, the transmembrane helices 2 and 5 are oriented towards the central pore (Murata *et al.*, 2000). It was expected that any change in the pore characteristics because of the altered TM2 and the TM5 would affect ammonia permeability in case there exists a central pore. All the chimeric proteins were nonfunctional and no protein expression could be determined in case of the altered TIP, because of the lack of an appropriate antibody. In case of NtPIP2, only the chimeric protein containing loop A and TM2 from the TIP was expressed (Fig 2.3.8). The other chimeras containing loop D/TM5 and both the previous swaps combined that is loop A/D as well as TM2/5 from the TIP were nonfunctional. The time courses for permeation are not presented here and were similar to the one given in the general figure 2.3.1 earlier in this section.

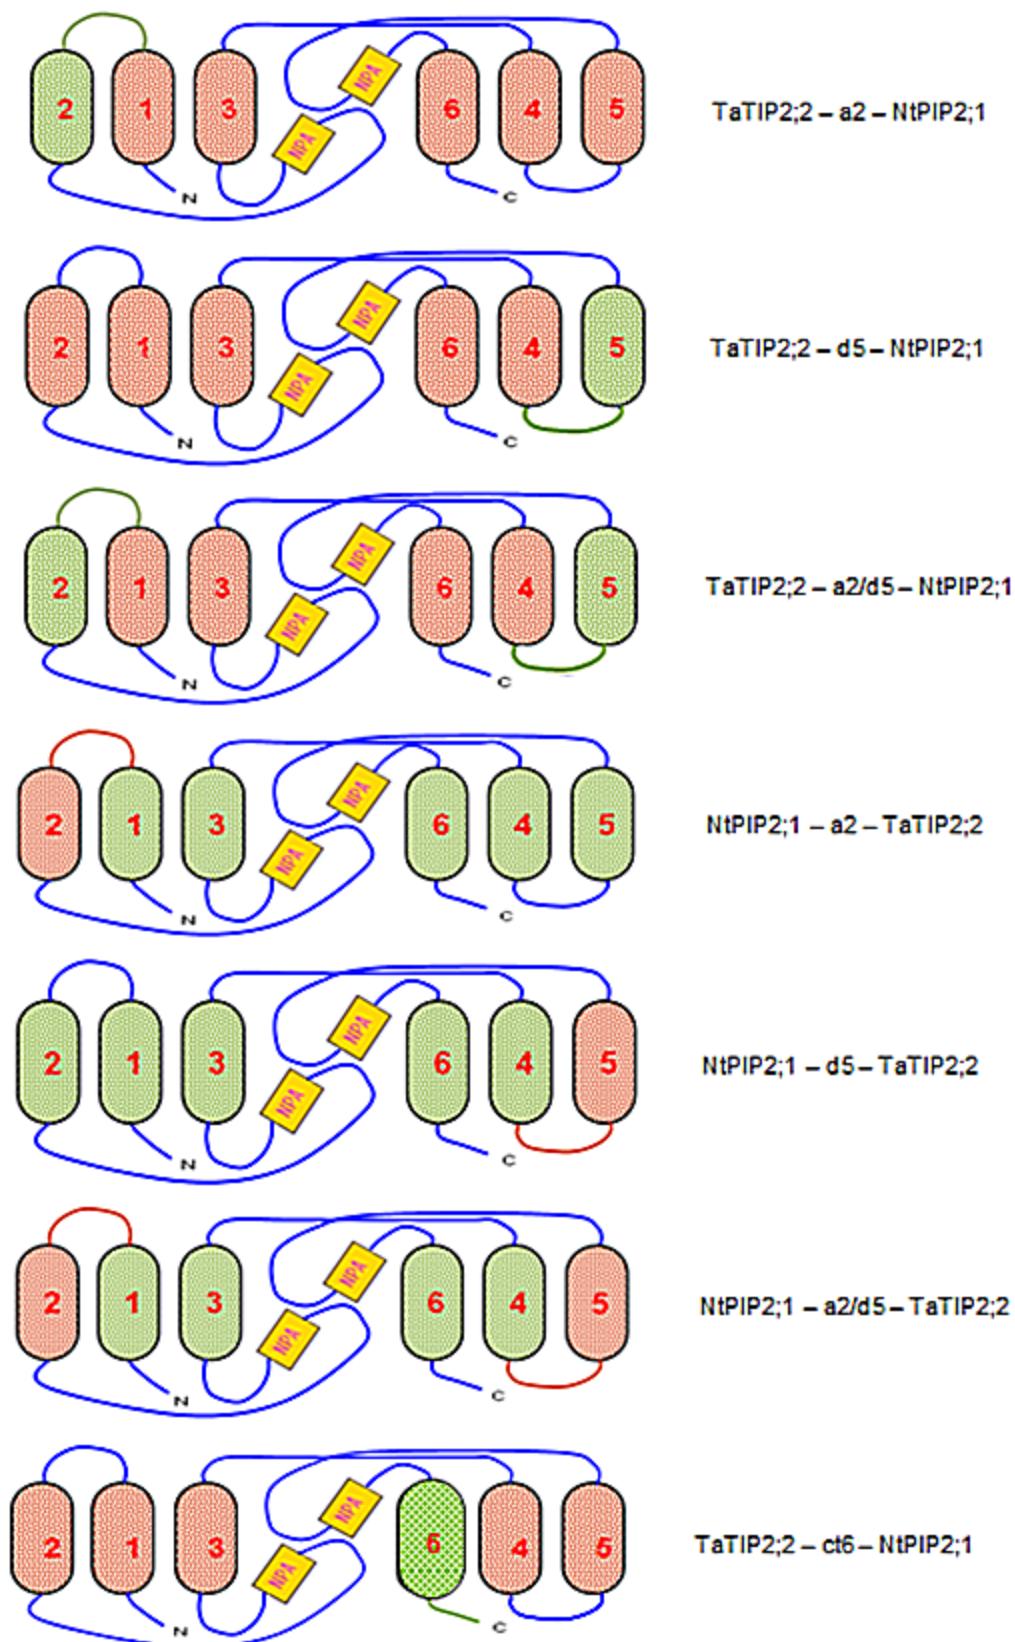

Fig 2.3.5: Topology of the chimeras generated between *TaTIP2;2* and *NtPIP2*. The keys on the right provide the details on the loops and the TM helices swapped; the alphabet in the middle stands for either the loop ("A" or "D") or for the C-terminus ("ct"), and the numeral

digit stands for the TM helix (“2”, “5” or “6”). For instance, TaTIP2;2-a2-NtPIP2 would read as the wild type TaTIP2;2 with its loop A and transmembrane helix 2 swapped corresponding to that of NtPIP2. The swaps in the domains of TIP and PIP were accomplished by a method termed as “splicing by overlap extension” (SOE-PCR) which involves a series of PCR reactions. The detailed strategy is explained in the chapter “Materials and Methods”.

There is no report available to date involving the domains swapping in plant AQPs. However, in an insect aquaporin AQPcic, the role of the distal part of the TM6 and the C-terminal part was studied by substituting the said domains with those of Glpf and no specific involvement of these regions was observed in tetramerization and channel selectivity (Duchesne *et al.*, 2002).

The molecular dynamics simulations (Jensen *et al.*, 2008) and the functional data (Nemeth-Cahlan *et al.*, 2004) revealed the existence of the pH-sensitive histidines in the extracellular loops A and C of the mammalian AQP0. These His residues contribute to pH-dependent regulation of AQPs, but the exact mechanism is to date unknown. It has been generally proposed in related studies that loop A may possibly undergo slight conformational changes, which are subsequently responsible for gating the pore. Water conductance of spinach PIP2 is regulated by phosphorylation of the two conserved residues, Ser115 and Ser247 (Johansson *et al.*, 1996, 1998), and by the protonation of the conserved His residues located in loop D of plant PIP2 (Tournaire-Roux *et al.*, 2003, Fischer and Kaldenhoff, 2008). Crystal structures of SoPIP2;1 in the open and the closed pore states further elaborated the involvement of loop D in the gating phenomenon (Törnroth-Horsefield *et al.*, 2006).

The contribution of loop D in mercury sensitivity has also been reported. Usually, the Hg sensitive site is located a couple of (usually 3) residues N-terminal to the second NPA motif but in case of AQP4, it is exceptionally located in loop D. The residue at the corresponding position in the orthodox human AQP1 is Thr157 and should be normally inaccessible from the intracellular side (Yukutake *et al.*, 2008).

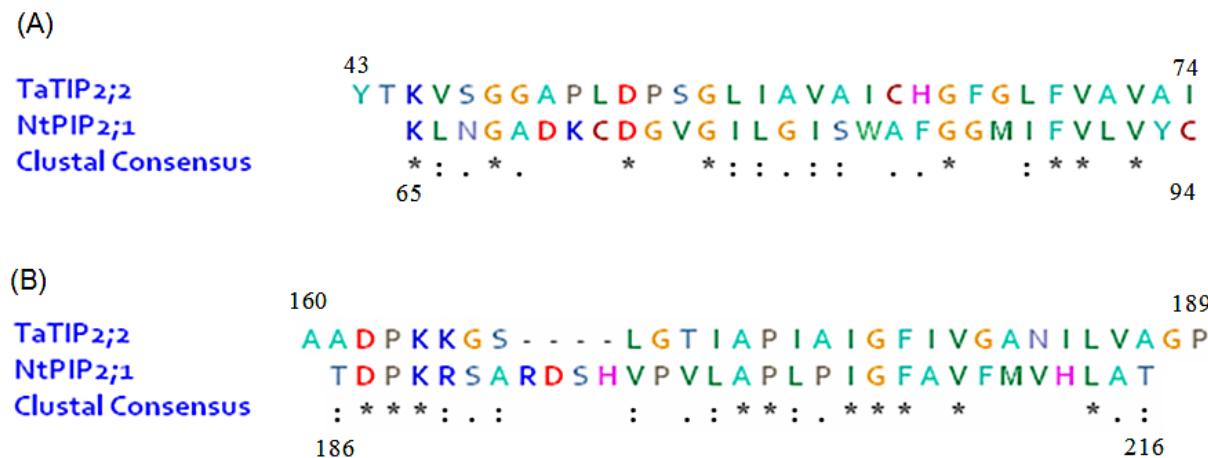

Fig 2.3.6: Partial sequence alignment in which loop A and TM 2 (**A**) and loop D and TM5 (**B**) domains of TaTIP2;2 and NtPIP2 are compared.

The helices TM2 and TM5 together with the C-terminal halves of the TM1 and TM4 form the major part of the surface of the aqueous pore. The rest of the surface is formed by loops B and E. It is believed that the interaction between the TM2 and the TM5 might be important, especially for the folding of the molecule because, the two helical bundles 1-3 and 4-6 might meet through interaction between TM2 and TM5 (Murata *et al.*, 2000). In AQP1, the A loop lies on top of helices 1 and 2, parallel to the side of the monomer. In SoPIP2, however, the position of the helix 1 C-terminus and the helix 2 N-terminus suggested that the loop A was oriented towards the center of the tetrameric topology (Kukulski *et al.*, 2005).

The crystal structure of AQP1 showed interaction between the TM2 and 5 by virtue of Gly residues; one each from both TM helices. Both helices are locked together in a so-called "fitting of ridges and grooves" manner (Murata *et al.*, 2000). The same positions were later found to be critical for anion permeability. Even minor alterations in the locking interactions of the TM2 and TM5 may cause conformational changes. Any substitution in the first position leads to the conversion of an anion channel into a water-selective channel and the double mutant failed even to traffic to the plasma membrane (Liu *et al.*, 2005a).

A. Homology models of a2 and d5 domains of TIP and PIP2

Based on the crystal structure as well as on functional data available to date, the importance of the loops A, D and the TM helices 2 and 5 has been discussed in detail throughout this study. It is quite obvious that even minor changes in the biochemical or the physical properties of these regions may result in noticeable variations in protein function.

The combined domains loop A and TM2 of TaTIP2;2 are 2 amino acids larger and are more hydrophobic than those of NtPIP2;1. An important feature of the given TIP domains is the presence of two proline residues as compared to none in PIP2. The proline rich TM2 indicates the role of this domain in the transport process. Also the two proteins are distantly related and the presence of prolines may be attributed to the conformational variations in these domains (Fig 2.3.6, 2.3.7).

Loop D and TM5 of NtPIP2 is only one amino acid larger and is less hydrophobic than that of TaTIP2;2. An important feature of this region is the presence of two positively charged Arg residues. This domain is enriched with proline residues in both channels, which is probably important because of its highly dynamic loop D. This loop in AQPs is involved in regulating the channels through the so-called gating mechanism. Loop D is capable to sway back and forth resulting into a flip-out mechanism over the pore mouth, which is responsible for its opening and closing. The gating mechanism has been reviewed in detail by Törnroth-Horsefield *et al.* (2010). The domain is also enriched with aromatic rings in case of NtPIP2, which indicates that this domain may play a role in recruitment of transporting solutes (Fig 2.3.6, 2.3.7).

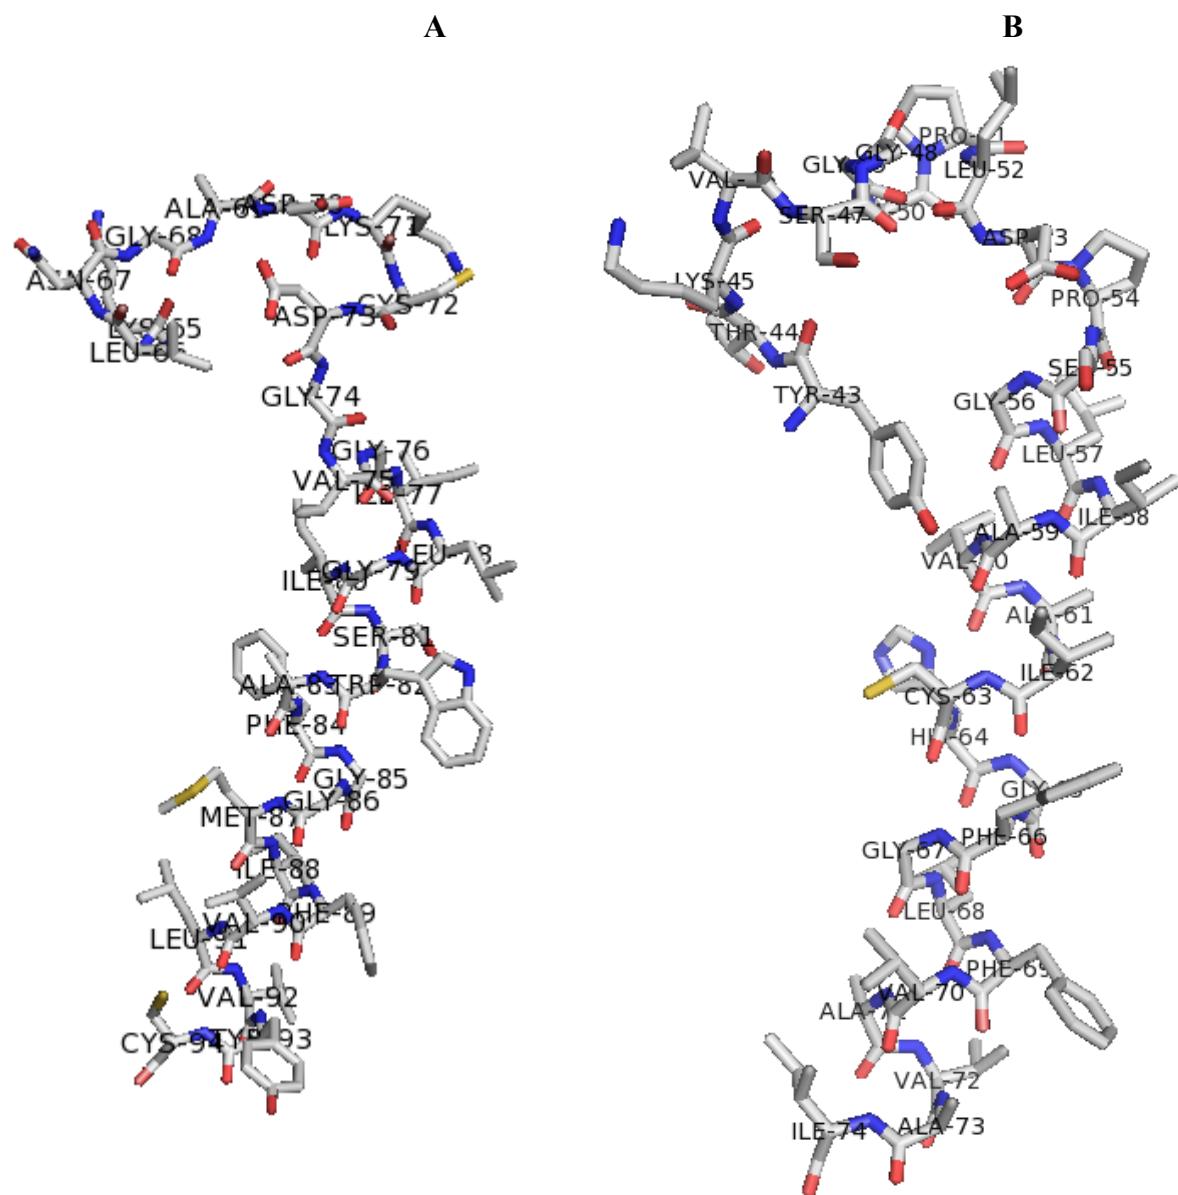

Fig 2.3.7: The structural domains loop A and TM2 shown in this figure were derived from the homology models of the swapped proteins that were drawn to confirm the structural integrity. **(A)** NtPIP2;1 **(B)** TaTIP2;2. The residues constituting the given domains have been labelled and the figure shows their Ca backbones and the side chains. The coordinates provided by the online tool “SWISS-MODEL” were used to draw the model in the software PYMOL. SWISS-MODEL used human AQP4 (PDB entry # 3GD8) and SoPIP2 crystal structures (PDB entry # 2B5F) as template for TaTIP2;2 and NtPIP2, respectively.

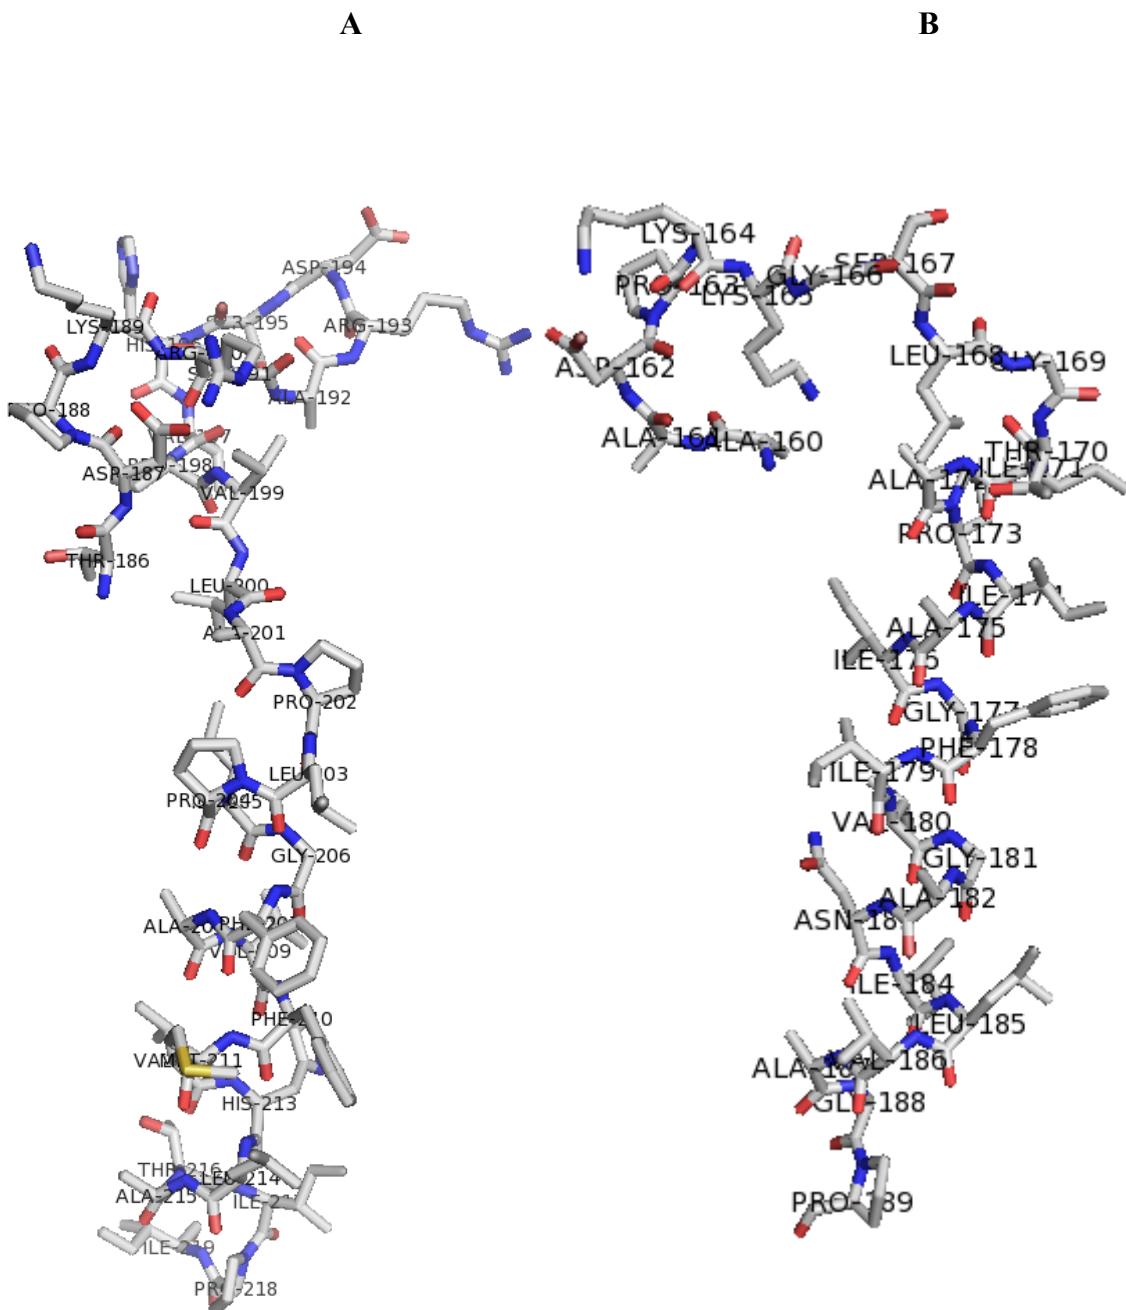

Fig 2.3.8: The structural domains loop D and TM5 shown in this figure were derived from the homology models of the swapped proteins that were drawn to confirm the structural integrity. (A) NtPIP2;1 (B) TaTIP2;2. The residues constituting the given domains have been labelled and the figure shows their α backbones and the side chains. The coordinates provided by the online tool “SWISS-MODEL” were used to draw the model in the software PYMOL. SWISS-MODEL used human AQP4 (PDB entry # 3GD8) and SoPIP2 crystal structures (PDB entry # 2B5F) as template for TaTIP2;2 and NtPIP2, respectively.

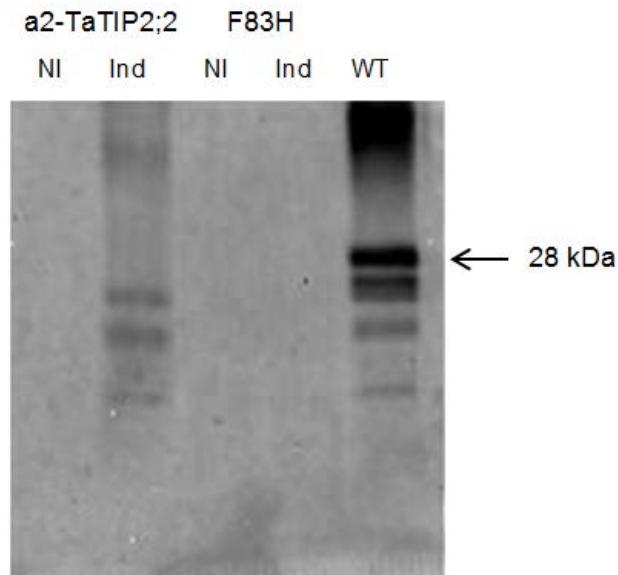

Fig 2.3.9: Western blot analysis of various PIP2 constructs expressed in yeast. F83H is a mutant in which corresponding residues in the ar/R region are substituted. a2-TaTIP2;2 is a NtPIP2 chimera in which loop A and TM2 have been substituted with those of TaTIP2;2. 10 µg of membrane protein from the cells expressing tobacco PIP2;1 were separated by SDS-PAGE and transferred to the nitrocellulose membrane. The wild type (WT) NtPIP2 served as a control.

2.3.2.2 Swapping the C-terminus together with TM6

In this experiment, the C-terminus along with the TM6 was attempted to be swapped between TIP and PIP2. These domains were successfully replaced in TIP, but in case of PIP2, the SOE-PCR reactions couldn't be accomplished. The TIP chimera didn't show any water/ammonia transport function (for kinetics, refer to the general figure 2.3.1 given earlier in this section). The result can't be readily interpreted as the protein expression couldn't be determined.

Most MIPs are >300 aa long, but there are examples of much larger proteins in this family, mainly of the eukaryotic origin. The larger size is primarily due to the extended N- and C-terminal domains, the poor conservation in these domains suggesting their involvement in regulation, rather than in function (Ball *et al.*, 2003). The role of the C-terminus has been suggested for sorting of the protein in AQP2 (Fushimi *et al.*, 1997) and AQP5 (Kosugi-Tanaka *et al.*, 2006).

The AQPs regulation by a gating mechanism has been reviewed in detail by Törnroth-Horsefield *et al.* (2010). These are the Ser residues (usually) present in the loop B which are responsible for gating the AQPs as a result of their phosphorylation.

A recent report suggested the involvement of the C-terminal Ser residue in AQP2 regulation that was owing to the conformational changes in the C-terminus to gate the channel (Eto *et al.*, 2010). The gating mechanism was thoroughly investigated with the help of the crystal structures in spinach PIP2 (Törnroth-Horsefield *et al.*, 2006) and in AQP5 (Horsefield *et al.*, 2008). Unusually, gating of a yeast aquaporin (Aqy1) was reported to take place by virtue of a N-terminal Tyr residue (Fischer *et al.*, 2009).

It is now well-established that membrane accumulation of AQP2 can be controlled by phosphorylation of the C-terminus. The modification of the C-terminus may interfere the trafficking of AQP5 (Ohashi *et al.*, 2008) and several studies have been reported to signify this role of the C-terminus in AQP2 (Moeller *et al.*, 2010) and AQP5 (Kosugi-Tanaka *et al.*, 2006). A couple of Ser residues are closely located in the C-terminus, out of which only one could be phosphorylated favouring the protein export from the endoplasmic reticulum in case of AtPIP2;1 (Prak *et al.*, 2008) and AQP2 (Hoffert *et al.*, 2008).

Hedfalk *et al.* (2004) reported a novel function for the C-terminal domain of Fps1p, an atypical member of the MIP family. The C-terminus regulated the channel as explained by the properties of the 12 residues constituting a part of the C-terminus right next to the last TMD.

The presence of Val276-Val-His-Val-Ile280 in the C-terminus was indispensable for targeting of AQP4 to the plasma membrane (Nakahama *et al.*, 2002). The C-terminal region has been proposed to be involved in AQP1 regulation, because it carries a consensus sequence for Ca^{2+} binding (Fotiadis *et al.*, 2002).

2.3.3 *Overview of the section*

The present study gives supportive evidence for the importance of the two selectivity regions. The ar/R region of TaTIP2;2 was sequentially mutated so that it mimicked that of NtPIP2;1. Surprisingly, even the single mutations in the ar/R region of TIP were impermeable to ammonia/water/protons. Unfortunately, only one of the mutants (that is F83H) in the ar/R region of both TIP and PIP2 was confirmed to be without any protein expressed. The results are in contrast to previous reports. A couple of the ar/R filter mutants reported so far (Beitz *et al.*, 2006) were functional (although they drastically changed the pore characteristics) and their association with protein sorting has not been established.

The previous reports suggest that protons are excluded by both the selectivity regions however, the main electrostatic barrier originates from the ar/R region. At the NPA

region, a positive electrostatic field originates from the two short α -helices, which restricts alkali cations (partially proton leakage too) through the pore. The removal of Asn at the NPA region and the alteration of the ar/R filter to increase its hydrophobicity reduce the electrostatic barrier and allow proton leakage through the pore. The ability of the NPA mutants in the present study to conduct protons is in agreement with the previous reports. However, there is readily no interpretation available for the loss of water/ammonia transport functions.

The crystal structure data as well as the results from the functional experiments have revealed the significance of some of the transmembrane helices and the connecting loops in AQP structure and function. TM helices 2, 5 and the loops A, D were swapped between ammonia conducting TaTIP2;2 and the predominantly water conducting channel NtPIP2;1 in a sequential manner. Further, it was also attempted to swap the C-terminus between the two channels. All the chimeric proteins were found to be nonfunctional for ammonia as well as for water transport. Among the PIP chimeras, protein was expressed only in case of the one with the swapped loop A and TM2. Unfortunately, no protein expression could be determined in case of the corresponding TIP chimeras due to the afore-mentioned reasons. The results imply remarkable structural differences between the two channels. Furthermore, no major alterations in the structural domains can be tolerated; any change would result in deleterious effects on structure/function of the AQPs.

3. MATERIAL & METHODS

3.1 Procedures and manipulations of DNA

3.1.1 Restriction endonuclease digestion of DNA

The restriction digestion was performed according to the instructions of the enzyme manufacturer (MBI Fermentas). One unit of enzyme (per μg of DNA) was added to the reaction mix and the DNA was digested in the recommended buffer. The digestion was allowed to occur for 4 hours to overnight at 37°C .

3.1.2 Agarose gel electrophoresis

Conventional agarose gels contained 0.8% agarose prepared in bidest water and ethidium bromide (0.05 $\mu\text{g}/\text{ml}$) was added to visualize the DNA. The gel was submerged into a chamber containing the running buffer (1x TAE buffer). The DNA samples were mixed with 1x loading buffer and loaded onto the gel. The electrophoresis was performed at a current of 35-45 mA (50–100 V). The DNA bands could be visualized by placing the gel under the UV light (302nm).

50 x TAE (1 L)	242 g	Tris, pH 8.0
	57.1 ml	Glacial acetic acid
	0.5 M	EDTA pH 8.0
5 x Loading Buffer	2 %	Ficoll 400
	0.5 %	SDS
	50 mM	EDTA
	0.2 %	Orange G
	10 %	Glycerin

3.1.3 Isolation / Purification of DNA fragments from agarose gels

Purification of PCR products/DNA fragments by directly using the kit was avoided, rather the following two-steps strategy was adopted: **(i)** The digested DNA (or the required DNA fragment) was isolated from the agarose gel by electrophoresis. The required band was cut using a sharp scalpel as it became visible under the UV light (302 nm) due to prior staining with ethidium bromide. The pieces of agarose gels were collected in a 1.5ml reaction tube. **(ii)** In order to isolate the required DNA fragment from the agarose, the gel extraction kit manufactured by Qiagen was used and the procedure recommended by the manufacturer was followed. At the final step, DNA was eluted into 20 μl of TE buffer (10 mM Tris-HCl, 1 mM EDTA, pH 8.0).

3.1.4 Determination of nucleic acid concentration

The DNA samples were diluted (1:50) and the absorption was measured at 260 nm and 280 nm on a photometer. The relative amount of the protein contamination in the sample was determined by calculating A_{260}/A_{280} ratio. A pure DNA preparation was desired to achieve a ratio between 1.8 and 1.9.

3.1.5 Polymerase Chain Reaction (PCR)

All PCR reactions were performed on the "Biometra T-Gradient" thermal cycler. A standard PCR reaction contained the following components:

50 ng	Template DNA
5 µl	10x Reaction buffer (Biotherm)
1 µl	dNTP-Mix (10 mM)
0.8 pmol	Sense-Primer (10 pmol/µl)
0.8 pmol	Antisense-Primer (10 pmol/µl)
1.5 mM	MgCl ₂
0.5 U	Taq-Polymerase (Biotherm, 5U/µl)
<i>Bidest. H₂O to 50 µl</i>	

Standard PCR program:

1. Initial denaturation	95°C	2 min
2. Denaturation	95°C	30 s
3. Annealing	55°C	30 s
4. Extension	72°C	6 min (1 min for every 1 kb)
<i>25x Cycle from step 2 to step 4</i>		

5. Final extension	72°C	10 min
	4°C hold	

3.1.6 Gene splicing by overlap extension (gene SOEing)

The principle of splicing by overlap extension (SOE) is based on the rejoining of two halves of the same gene with the "overlap" containing the altered sequence, or the joining of two unrelated sequences. This method is useful for joining even three segments. This recombination involves a series of PCR reactions as illustrated in Fig 3.1. It is accomplished in three separate polymerase chain reactions: (i) During two independent PCRs, the splices AB and CD are generated using the primers a, b and c, d, respectively. The primers add the sequences at the fusing ends of the products AB and CD so that the products are complementary to each other. (ii) After purification of both fragments, a final PCR is performed; splices AB and CD would produce the recombinant product AD. The recombinant product is cloned into the vector using the appropriate restriction sites, which are introduced into the recombinant product by the outer primers (a and d).

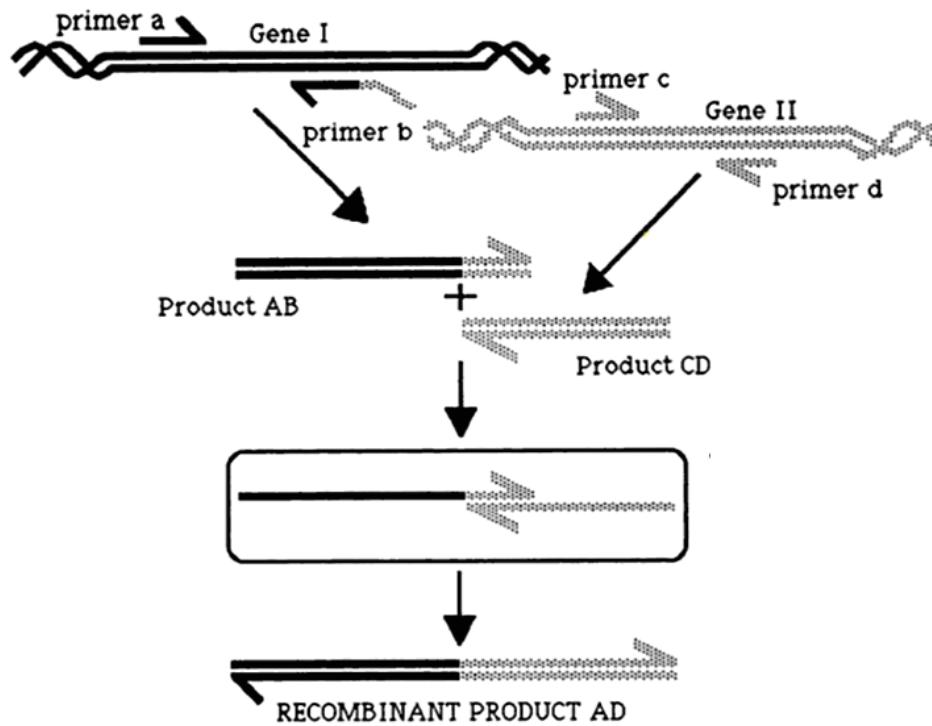

Fig 3.1: Schematics for of the general procedure of gene splicing by overlap extension (SOEing). Adopted from: Horton (1993).

3.1.7 Site-directed Mutagenesis

Site-directed (or specific) mutagenesis is a molecular biology technique in which a mutation is created at a defined site in a DNA molecule, usually a plasmid. For accomplishing site-directed mutagenesis in the DNA sequences, a “QuickChange® Site-Directed Mutagenesis Kit” was used. The procedure recommended by the kit manufacturer (Stratagene) was followed.

The thermal cycling reaction was set as follows:

Template DNA	50 ng
10x buffer	5 µl
dNTP's (10mM)	1 µl
Forward Primer (5 pmol)	1 µl
Reverse Primer (5 pmol)	1 µl
<i>Pfu</i> polymerase (3 U/ml)	0.5 µl
<i>Bidest. H₂O to 50 µl</i>	

The thermal cycling program was as follows:

- | | | |
|-------------------------|------|-------|
| 1. Initial denaturation | 95°C | 2 min |
| 2. Denaturation | 95°C | 30 s |

3. Annealing	55°C	30 s
4. Extension	72°C	6 min (1 min for every 1 kbp)
5. Cycle from step 2 to step 4		25x
6. Final extension	72°C 4°C hold	10 min

After thermal cycling, the reaction was cooled down on ice for 2 min. The restriction enzyme DpnI (10U) was added to the reaction tube to digest the methylated, non-mutated, double stranded DNA. The digested reaction was incubated at 37°C for 1 hour.

3.1.8 Ligation of DNA fragment

The final reaction volume for ligation was set at 10 µl. 50 ng vector DNA along with the required amount of insert DNA (in a molar ratio ranging from 1:1 up to 1:5) were added into the ligation reaction. The amount of insert DNA was determined with the help of the following formula:

$$DNA[pmol] = \frac{2 \times 10^{-6} \times DNA[\mu g]}{DNA[bp] \times 660Da}$$

The following reaction was set:

Linearized vector DNA	50 ng
DNA Insert	x ng
10x T4 Ligase buffer	1 µl
T4 DNA Ligase	0.5 U
<i>H₂O to 10 µl</i>	

The reaction mixture was incubated at 16°C for 6 hours to overnight. As a control, a reaction was set exactly as mentioned above but without the insert DNA. Almost 5µl of the ligated mixture was used for transforming the bacterial cells.

3.1.9 Sequencing of DNA fragments

The DNA sequencing required highly pure DNA. The commercial services of Seqlab and Starseq (based respectively in Göttingen and Mainz, Germany) were used for DNA sequencing and the reactions were prepared according to the instructions. The recommended amount of DNA along with the primer specific to the PCR product were added into a 200 µl reaction tube to prepare the sample.

3.2 Procedures and manipulations of *E. coli*

3.2.1 *E. coli* strains used in the study

<u>Strain</u>	<u>Genotyp</u>	<u>Supplied by</u>
XL1 blue	recA1 endA1 gyrA96 thi-1 hsdR17 supE44 relA1 lac [F' proAB lacIqZΔM15 Tn10 (Tetr)]	Protagen
DH5α	F'- endAI hsdRJ7 (r-, mit) supE44 thi-1 λ- recA1 gyrA96 relAI deoR A(lacZYA-argF)- U169 Φ80dlacZΔM15	Invitrogen

3.2.2 Media for cultivation and transformation of *E. coli*

LB Medium*	1% Tryptone 0.5% Yeast extract 0.5% NaCl set pH at 7.5 <i>Volume raised to 1 L with bidest H₂O</i>
Antibiotic for selection:	50 µg/µl Ampicillin
SOC Medium*	2% Tryptone 0.5% Yeast extract 10 mM NaCl 2.5 mM KCl 10 mM MgCl ₂ 10 mM MgSO ₄ 20 mM Glucose set pH at 7.0

*1% agar was added for semi-solid media

3.2.3 Preparation of chemically competent *E. coli* cells

A single bacterial colony was picked to inoculate 3 ml of the LB media. The bacteria were grown overnight in a test tube placed on a shaking incubator set at 37°C. The bacterial pre-culture was diluted with 400 ml of the LB media in a large 2 L flask to have a good ratio between the surface and the volume and was grown with vigorous shaking until OD₅₅₀ = 0.48 (2-2.5 h). Then bacterial suspension was poured into 50 ml falcon tubes, chilled on ice for 15 min and centrifuged at 4,000 rpm for 10 min at 4°C. All further steps were performed in a cold room and on ice. The harvested bacterial cells were resuspended in 20 ml of 0.1 M CaCl₂ solution, incubated on ice for 2 hours and centrifuged again as mentioned above. The pellet was resuspended in 43 ml of 0.1 M CaCl₂ and 7 ml of sterile glycerol. Finally the cells were dispensed

into aliquots of 250 µl and were shock-frozen using liquid nitrogen before storage at -70°C.

3.2.4 Heat-shock transformation of *E. coli* cells

For transforming the *E. coli* with the required construct, 50 µl of the competent cells were thawed on ice. Either 5 ng of the sample DNA or 5 µl of the ligation reaction mixture was added to the competent cells in the reaction tube and gently mixed by swirling. The tubes were incubated on ice for 20 min. Cells were heat-shocked in a 42°C water bath for 45 sec and immediately cooled on ice for 2 min.

The transformed bacterial cells were then mixed with 1 ml SOC medium and the tubes were transferred to the shaking incubator set at approx. 225 rpm at 37°C for 45 min. Finally, the transformed bacteria (100-200 µl) were plated on a petri dish containing semi solid LB medium supplemented with the antibiotic (100 µg/ml ampicillin) required for positive selection and incubated at 37°C for 18 hrs.

3.2.5 Plasmid isolation from *E. coli* cells (miniprep)

3 ml of LB Media was inoculated with a single bacterial colony. The culture was grown overnight in a test tube. The cells were transferred into 1.5 ml reaction tubes and harvested by centrifugation at 13,000 rpm for 30 seconds. The supernatant was completely removed and the cells were resuspended in 300 µl of the Resuspension Buffer. 300 µl of the Lysis buffer was added into the reaction tube and the bacterial suspension was gently mixed by inverting it 10-15 times. The cell lysis required 5 minutes of incubation at RT. The neutralization of the cell lysate was achieved by adding 300µl ice-cold Buffer III. The suspension was again gently mixed and incubated for 10 min on ice.

The samples were centrifuged at 13,000 rpm for 10 min at RT. The genomic DNA as well as the proteins were pelleted during this centrifugation step. Almost 700 µl of the supernatant volume was transferred to a 1.5 ml reaction tube containing 800 µl of isopropanol. The DNA pellet was washed twice with 70% ethanol in order to remove the salts. The pellet was air-dried at RT and the DNA was eluted with 20 µl of bidest water. The plasmid preparation was stored at -20°C.

Solution I (Cell Resuspension buffer)

50 mM	Tris/HCl pH 8.0
10 mM	EDTA
100 µg/ml	RNaseA

Solution II (Alkaline Lysis Solution)

200 mM	NaOH
1%	SDS

Solution III (Neutralization Solution)

3 M Potassium acetate pH 5.5

3.3 Procedures and manipulations of yeast

3.3.1 *Saccharomyces cerevisiae* strains used in the study

The *Saccharomyces cerevisiae* strain 31019b (if not otherwise mentioned) was used in the present study which had the following genotype:

MAT_a, ura3, mep1Δ, mep2Δ::LEU2 mep3Δ::kanMX2 (Marini *et al.*, 1997)

3.3.2 Cultivation of yeast cultures

Culturing yeast for various purposes:

The non-transformed yeast cells were cultivated in either liquid or semi-solid YPD medium for various purposes. The yeast cultures meant for permeability measurements on the stopped-flow spectrometer were grown for a definite induction period using the appropriate selection medium [SC + gal (-Ura)]. When no induction of the protein expression was required, the media contained glucose instead of galactose. The time taken for the yeast to attain the NtPIP2 expression at its peak was already determined in the lab. Regarding TaTIP2;2, preliminary experiments had to be performed but the data are not presented. The cells were grown under continued shaking at 225 rpm at a temperature of 30°C.

Media Composition:

YPD medium*	1% Bacto yeast extract 2% Bacto peptone 2% Glucose
SC+gal (-Ura) Medium* (1l)	0,17% Yeast Nitrogen Base 0,5% Ammonium sulfate 0,115% -Ura Amino acids Mix 2% Galactose
SC+glu (-Ura) Medium* (1l)	As above, except the Galactose was substituted with 2% Glucose
10 x amino acids mix (- Ura)	0.01% Adenine, Arginine, Cysteine, Lysine, Threonine, Leucine 0.005% Aspartate, Histidine, Isoleucine, Methionine, Phenylalanine, Proline, Serine, Tyrosine, Valine

* To prepare the semi-solid media, 1.5% agar was added

3.3.3 Isolation of plasmid DNA from yeast

The procedure of Robzyk and Kassir (1992) was followed. 1.5 ml of the overnight culture was grown in a selection medium. The cells were harvested and resuspended in 100 µl STET solution. 0.2 g glass beads (ϕ 0.5 mm, Sigma) were added to the cell suspension. The cells were vigorously vortexed for 5 minutes before another 100 µl of STET solution were added and the reaction tube was incubated in boiling water bath for 3 min. After brief cooling, the tube was centrifuged at 13,000 rpm for 10 min at 4°C. 100 µl of the supernatant were transferred to a fresh tube containing 50 µl of 7.5 M ammonium acetate, incubated at -20°C for 1 hour, and centrifuged for 10 minutes at 4°C. 100 µl of the supernatant were added to 200 µl of ice-cold ethanol. Cells were spun down, washed with ethanol and resuspended in 20 µl of bidest water. 10 µl of this solution were used to transform the competent bacteria.

<i>STET Solution</i>	8 %	Saccharose
	50 mM	Tris/ HCl pH 8.0
	50 mM	EDTA
	5 %	Triton-X 100

3.3.4 Biostatic transformation of yeast cells

The yeast cells were transformed with the required plasmid DNA through the biostatic method following the protocol of Sanford *et al.* (1993). A particle delivery system (PDS) 1000/He (Bio-Rad Labs, USA) was used for this purpose. Briefly, a single colony was inoculated on a petri dish containing semi-solid YPD media and grown for 48 hours at 30°C. The microcarriers (Tungsten particles) were washed with ethanol through a series of steps and could be stored for a period of 2 weeks at 4°C. The DNA coating was accomplished by mixing 50 µl of microcarriers, 5 µg (in 5 µl volume) of plasmid DNA, 50 µl of 2.5 M CaCl₂ and 20 µl of 100 mM freshly prepared spermidine solution. The particles had to undergo a series of washing steps using ethanol before these were ready for bombardment. The suspension of 10 µl DNA-coated gold particles was placed on the microcarrier plate and air-dried. The overnight wild-type yeast culture was harvested by centrifugation at 3,000 rpm for 3 min. After washing with bidest water, the cells were again resuspended in water. 80 µl of the cell suspension was spread on the petri dish containing an appropriate selection media. After drying, the plates were placed at a recommended distance from the microcarriers inside the vacuum chamber of the particle gun. The particles were finally bombarded on the yeast cells using a helium pressure of 1100 psi under a vacuum of 3.6 MPa.

3.3.5 Estimation of cytosolic pH in yeast cells

The ratiometric pH determination method (Slavik, 1982) was followed to determine the cytosolic pH. The technique is based on the selective excitation of 2 forms of

fluorescein, basic (monoanionic) and acidic (dianionic). Each of these forms possesses different fluorescence properties. The proportion of these 2 forms is pH-dependent and may be monitored by the ratio of fluorescence intensities observed following excitation at 435 nm and 490 nm.

The ratiometric pH determination is particularly reliable in case of turbid solutions where fluorescence intensity fluctuates due to excitation and emission light scattering. The advantage of this method is that the ratio of fluorescence intensity is not sensitive to fluctuations of light scattering.

3.3.5.1 The fluorescent dye “Fluorescein diacetate” (FDA)

Fluorescein is an aromatic heterocyclic molecule the applications of which range from forensics to microscopy utilizing its fluorescence properties. An important use of Fluorescein is measurement of intracellular pH. As the Fluorescein leaks out of the cells rapidly, highly charged derivatives are recommended (Lakowicz, 2006). Fluorescein has a pK_a of 6.4, and its ionization equilibrium leads to pH-dependent absorption and emission over the range of 5 to 9. The absorption and emission spectra of fluorescein are shown in Fig 4.2.

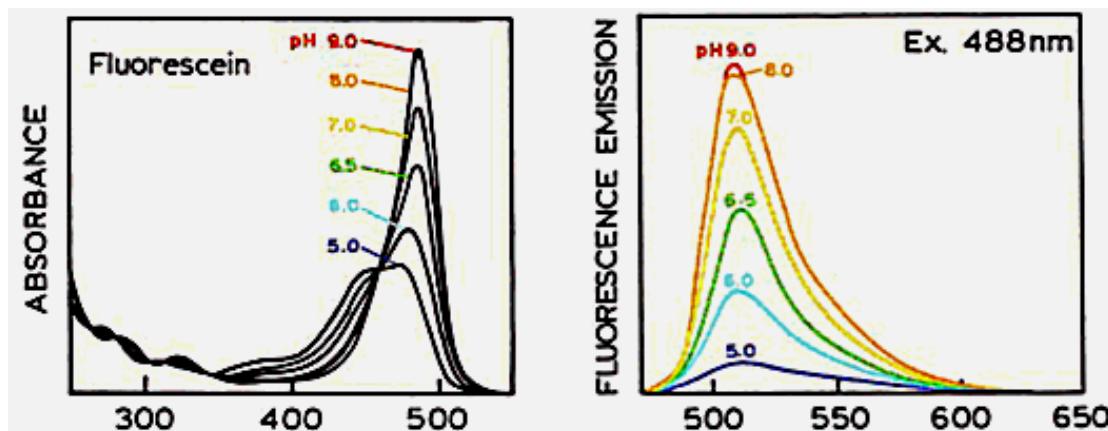

Fig 4.2: Absorption and emission spectra of Fluorescein. Adopted from Lakowicz (2006)

Fluorescein is a complex fluorophore which, depending on pH, exists in one or more of four different prototropic forms that is cation, neutral, monoanion and dianion. However, in the pH range 6-10, only the monoanion-dianion equilibrium prevails. Only these two forms of fluorescein are fluorescent and their maximum excitation occurs at 494 nm and emission at 521 nm (probes.invitrogen.com). In aqueous solutions with pH above 9, its phenol and carboxylic acid functional groups are both totally ionized. Upon acidification, first the phenolic group is protonated to yield the monoanion ($pK_a \approx 6.4$) followed by the carboxylic acid ($pK_a < 5$) yielding neutral fluorescein species. Upon further acidification, a cation form ($pK_a < 2.1$) will be generated (Bamfield, 2001).

3.3.5.2 Plotting a calibration curve

For measuring the apparent changes in cytosolic pH of *Saccharomyces cerevisiae* cells, a colorless membrane permeable diacyl derivative of Fluorescein (Fluorescein diacetate; Sigma catalog no. F7378) was used, because of the following reasons: (i) It does not show fluorescence as such but, only after decomposition to fluorescein through intracellular esterases. (ii) Fluorescein shows low membrane permeability and data can be comfortably recorded for several minutes without risk of dye leakage out of the cell.

For each pH, the emission intensity was detected at 520 nm. A ratio of light emission at 520nm was determined for excitation at ~490 nm versus the excitation at its isosbestic point of ~435 nm. The ratio of these two intensities ($I_{490/435}$) was plotted against pH on a logarithmic scale (see Fig 2.1.10 in results section). The data were fitted with a second-order polynomial function (see Fig 2.1.10 in results section). The results were used to generate an equation that converted recorded fluorescence ratio in case of yeast cells to apparent pH_i values.

For obtaining data for the calibration curve, McIlvaine buffers were prepared with pH varying from 5 to 9.

McIlvaine Buffer	0,2M	Disodium hydrogen phosphate (Na_2HPO_4)
	0,1M	Citric acid ($C_6H_8O_7$)

3.3.5.3 Estimation of cytosolic pH

Yeast cells from an overnight culture (20ml) were harvested by centrifugation and loaded with Fluorescein. 5ml of loading buffer and Fluorescein diacetate (at an end concentration of 50 μ M) were added to the yeast cells (pellet) and were placed on a shaking incubator set at 125 rpm for 15 min at 30°C. The cells were washed twice with bidest water and resuspended in the incubation buffer (as given under the caption 3.4.2.3, ammonia permeability buffers). Fluorescence intensities ($I_{490/435}$) were recorded before and immediately after addition of 25mM NH_4Cl , in order to obtain apparent values for starting and final pH, used for calculating P_{NH_3} values.

3.4 Determination of Permeabilities

3.4.1 Stopped Flow Spectrophotometer

A schematic diagram of the stopped-flow spectrophotometer is given in Fig 3.3. The two syringes of the apparatus are filled with yeast cells (suspended in incubation buffer) and the mixing buffer (represented as solution A and B, respectively in the Fig 3.3). The solutions inside the syringes are compressed to force their mixing in a cuvette (observation cell). From here, the mixed solutions are forced out to pass into the stop syringe. The plunger of the stop syringe hits the stopping block to terminate the mixing process. The flow fills the stop-syringe, until the plunger hits the trigger-

switch. This simultaneously stops the flow and starts the data acquisition. The progress of the reaction is monitored in the observation cell using the emission measured at a 90° angle to the excitation beam (Nalefski and Newton, 2003).

An important feature of the stopped-flow technique is to record the absorbance within milliseconds of mixing the two reactants. In addition, the stop syringe assures for a steady rate of flow so that the reactants can be added to the solution and the products are formed at a consistent rate.

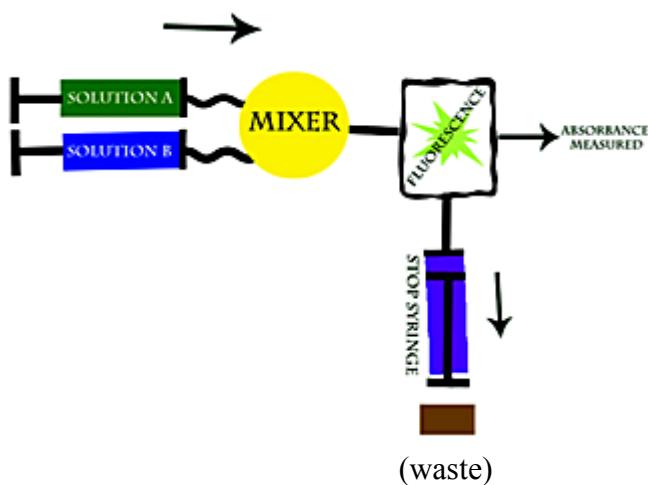

Fig 3.3: Schematic diagram of the stopped-flow apparatus.
Adopted from: <http://chemwiki.ucdavis.edu/>

3.4.2 Determination of Ammonia Permeability

3.4.2.1 Principle

According to the Henderson-Hasselbalch equation, at pH 8.0 more than 80% of ammonia will be in the NH_3 form (which is a slightly basic ammonia species). Therefore, the intracellular pH will increase as a result of ammonia uptake through the membrane. The change in intracellular pH corresponds to changes in the fluorescence intensity which are recorded by the stopped-flow spectrophotometer and are shown graphically on the Biokine software.

3.4.2.2 Loading of yeast cells with Fluorescein diacetate (FDA)

20 ml of the overnight culture was raised and the cells were harvested at 3,000 rpm for 3 min at RT in a table-top centrifuge. The pellet was washed twice with bidest water. After the final centrifugation, cells were resuspended in 5 ml of loading solution and were placed on a shaking incubator set at 125 rpm and 30°C. After 15 minutes, cells were loaded with fluorescein, giving them a yellow color. The cells were quickly spun down at 3,000 rpm at 4°C. The loading solution was completely removed and the cells were resuspended in the appropriate incubation buffer. The cells were kept on ice until the measurements were started.

<i>Loading Solution</i>	50 mM	HEPES/NaOH	pH 7.0
	5 mM	2-Deoxy-D-Glucose	
	50 µM	FDA	

3.4.2.3 Experimental Conditions

All the measurements were performed at a temperature of 10°C, that was maintained by using a circulating water-bath. The yeast cells loaded with fluorescein were mixed with an equal volume (100 µl) of the mixing buffer. The velocity of the flow was set to 10 ml/s. The instrument's dead time was estimated to be 1.6 ms. The dead time is defined as the time from mixing the reactants to the beginning of the recording.

Light source	λex: 490 nm		
Time base 1 =	20 µs/data point	for	4000 data points
Time base 2 =	200 µs/data point	for	2000 data points
Time base 3 =	2 ms/data point	for	1000 data points
Filter	300 µs		

Ammonia permeabilities were analysed by measuring pH dependent fluorescence changes using a 515 nm cut-off-filter for light emission and excitation at 490 nm.

Buffer Composition:

<i>Incubation Buffer</i>	50 mM	NaCl	
	10 mM	Tris/HCl	pH 8.0
	5 mM	CaCl ₂	
<i>Mixing Buffer</i>			
	50 mM	NH ₄ Cl	
	10 mM	Tris/HCl	pH 8.0
	5 mM	CaCl ₂	

3.4.3 Determination of Water Permeability

3.4.3.1 Principle:

The measurement of water transport was based on changes in the volume of the yeast protoplasts and the subsequent effect on the intensity of the scattered light. An osmotic gradient of 300mOsmol was generated across the plasma membrane by mixing the protoplast suspension with the hypotonic solution (mixing buffer) resulting in water influx and swelling of the protoplasts. The incident light after striking with the protoplasts surface is scattered and the photomultiplier detects the scattered light intensity from a right angle (Fig 3.3). More the cells are swollen, more would be the surface area of protoplasts and less would be the scattering of light.

3.4.3.2 Preparation of yeast protoplasts:

The procedure reported by Bertl *et al.* (1998) was adopted to prepare the yeast protoplasts. The cell wall was digested by using Zymolyase. Zymolyase, derived from *Arthrobacter luteus*, is a purified mixture of β -glucanases and proteases. The ingredients of this mixture work in conjunction for an efficient cell wall degradation. As the Zymolyase may damage the membrane proteins, bovine serum albumin (BSA) was added which acts as a competitive substrate for the proteases. The procedure for protoplast preparation was as follows:

10 ml from an overnight yeast culture were harvested at 3,000 rpm for 3 min in a Beckmann tabletop centrifuge at RT. The cells were washed with distilled water, resuspended in 3 ml of incubation buffer and placed on a shaking incubator set at 200 rpm and 30°C for 15 min. After that, 4 ml of the protoplast buffer was added to the suspension along with zymolyase 20T and BSA (end concentration are given below). The suspension was incubated for 45 min and 30°C on a shaker set to 200 rpm. The protoplast suspension was centrifuged at 3,000 rpm for 3 min at RT and resuspended in the appropriate incubation buffer for subsequent stopped-flow measurements.

<i>Incubation buffer</i>	50 mM	KH ₂ PO ₄ (pH 7.2 adjusted with KOH)
	0.2%	β -Mercaptoethanol
<i>Protoplast buffer</i>		Incubation buffer with 2.4 M Sorbitol
	0.01-0.03 mg/ml	Zymolyase (20T)
	25 mg/ml	BSA

3.4.3.3 Experimental Conditions:

Water transport was measured using light source set at a wavelength of 436nm. The other experimental conditions were same as previously mentioned for the ammonia measurements.

<i>Incubation Buffer</i>	1.8 M	Sorbitol
	50 mM	NaCl
	5 mM	CaCl ₂
	10 mM	Tris/HCl pH 8.0
<i>Mixing Buffer</i>	Same as above except Sorbitol concentration was 1.2 M	

3.4.4 Data Analysis

3.4.4.1 Calculation of osmotic permeability coefficient (P_f)

For each of the constructs, at least 50 time courses were obtained from at least three independent stopped-flow measurements, which involved independent batches of yeast cultures. The traces were analyzed using the software “Biokine” version 4.27 (Bio-Logic Science Instruments, France). Using this software, the kinetics were analyzed by fitting them using single exponential function. The data fitting provided rate constants (k_i) required to calculate the permeability coefficients, which can be used to compare (transport) function of various constructs. For water transport curves, data were analyzed for a time period of 100 ms after its beginning (see Fig 3.4 for further details). The software employed “Simplex” algorithm to fit the time courses. The equation is given as:

$$Y = at + b + \sum_{i=1}^N c_i e^{-k_i t}$$

In this equation, the portion ($at + b$) represents the linear component of the reaction whereas the remaining portion represents the sum of exponential functions.

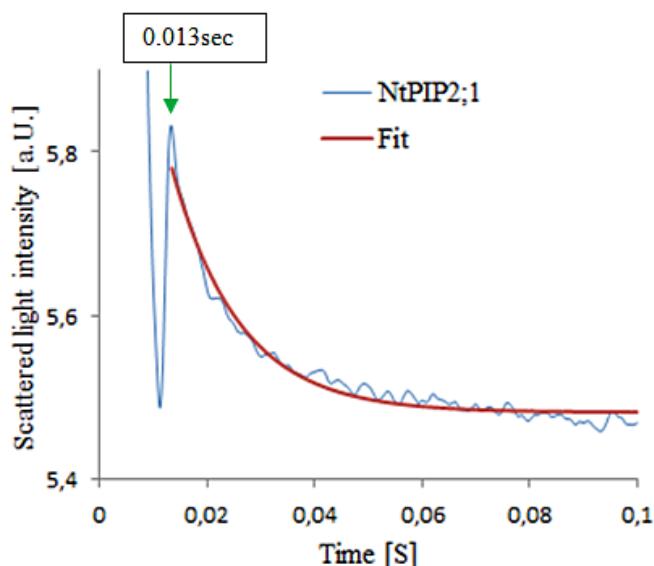

Fig 3.4: Graphic representation of the exponential fit of a typical water transport curve. The arrow indicates the starting point for the “fit” procedure. Only that part of the time course is shown that was used to calculate the rate constant (k_i).

The coefficients of the ammonia (P_{NH_3}) and the osmotic permeability (P_f) serve as the unit for the transport efficiency [cm/s] of the respective solutes through a membrane. Using the k_i values, the coefficients of osmotic permeability were calculated by the following equation (van Heeswijk and van Os, 1986):

$$P_f = k_i \cdot \frac{V_o}{S_o \cdot V_w \cdot C_{out}}$$

In the above equation, k is the fitted exponential rate constant, V_w is the molar volume of H_2O , V_0 and S_0 are the initial mean volume und the initial mean surface area of the protoplasts, respectively. C_{out} is the external osmolarity.

3.4.4.2 Calculation of ammonia permeability coefficient (P_{NH_3})

For ammonia transport curves, the data were fitted using single exponential function for the time period of 2 seconds (see Fig 3.5 for further details). The coefficients of the ammonia permeability were calculated by the following equation (Yang *et al.*, 2000):

$$P_{\text{NH}_3} = \frac{1}{\tau} \left[\left(\frac{S}{V} \right) / 10^{(pH_f - pK_a)} \right]^{-1}$$

(Units are cm/s)

In this equation, S is the surface ($S = \pi r^2$) and V is the volume ($V = 4/3 \cdot \pi r^3$) of the yeast protoplast. τ is the time constant, pH_f is the final pH and pK_a of ammonia is 9.24. Surface and volume of the cells were calculated from the cell diameter ($5\mu\text{m}$) determined through microscopical measurement.

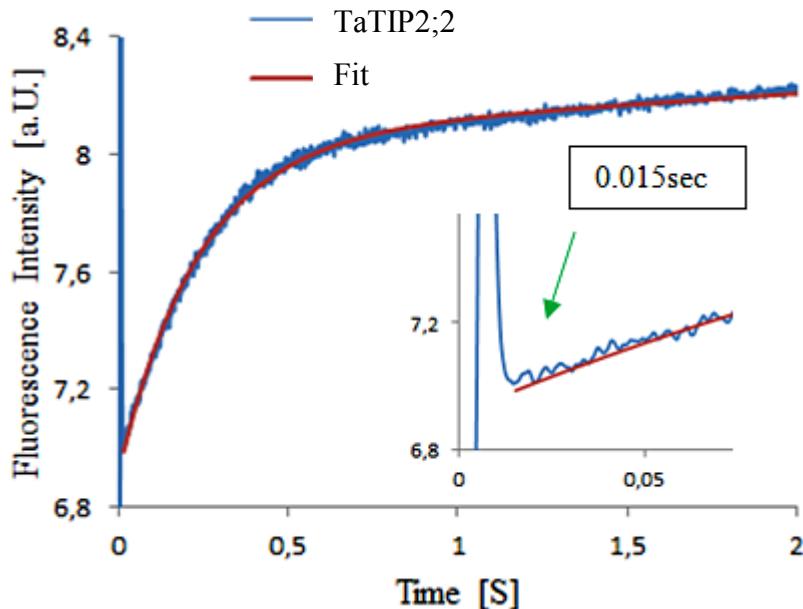

Fig 3.5: Graphic representation of the exponential fit of a typical ammonia transport curve. The arrow (inside the inset) indicates starting point for the “fit” procedure. Only that part of the time course is shown that was used to calculate the rate constant (k_i).

3.5 Procedures and manipulations of proteins

3.5.1 Isolation of membrane proteins from yeast

Yeast cells from an overnight culture were harvested by centrifuging at 500 xg for 3 min at RT and washed with bidest water. For each gram of yeast cells, 3 ml of homogenization buffer and an equal volume of chilled and acid-washed glass beads (ϕ 0.5 mm, Sigma) were required. The cells were vortexed for a total of 20 min with repeated vortexing and subsequent cooling on ice, each for 1 min periods.

The homogenate was centrifuged at 2,500 xg at 4°C for 5 min to remove cell debris. In order to sediment the membranes, the supernatant was centrifuged in an ultracentrifuge (Sorvall Discovery M120) at 50,000 xg at 15°C for 15 min. The membrane pellet was resuspended in 250 μ l of TB buffer.

Homogenization Buffer

50mM	Na ₃ PO ₄	pH 7.5
1mM	EDTA	
5%	Glycerin	
1 μ g/ml	Leupeptin	
1 μ g/ml	Pepstatin	

TB Buffer

10mM	Tris/HCl	pH 7.5
1mM	DTT	

3.5.2 Determination of protein concentration

Protein concentration was determined according to the Bradford method (Bradford, 1976), which exploits the deprotonation of the “Coomassie Brilliant Blue G-250” (CBBG) dye upon binding to protein. The dye exists either in the cationic form (red color) or in the anionic form (blue color). Under the acidic environment of the reagent, the coomassie dye changes its color from brown to blue in proportion to the amount of the protein. Protein binding (primarily with arginine, lysine and histidine) results into a spectral shift from the reddish form of the dye (absorbance maximum at 465nm) to its blue form (absorbance maximum at 595nm). The increase of absorbance at 595 nm is proportional to the amount of dye bound with the protein which indicates the amount of the protein present in the sample.

Protein concentration in the sample is determined by comparison to the color response of the protein assay standards, usually prepared as a series of known dilutions of bovine serum albumin (BSA). Bovine serum albumin (BSA) in 0.5 M NaOH was used as the standard. For determination of the protein concentration in an unknown sample, 1 ml of Bradford reagent (Carl Roth GmbH) was mixed with 1 μ l of the sample, incubated for 5 min at room temperature and the absorbance was

determined at 595 nm. A standard curve was obtained by plotting the absorbance (595 nm) of the standards (y-axis) versus their concentration in µg/ml (x-axis).

3.5.3 SDS-Polyacrylamide gel electrophoresis (SDS PAGE)

Sodium dodecyl sulfate (SDS) is an amphipathic detergent. SDS causes proteins to denature and disassociate from each other. SDS-treated proteins have very similar charge-to-mass ratios and similar shapes. During PAGE, the rate of migration of the SDS-treated proteins is effectively determined by the molecular weight. In the presence of SDS, the intrinsic charge of a protein is masked. Resolving the proteins in a discontinuous SDS-PAGE offers the advantage, that the proteins migrate quickly through the stacking gel and are squeezed down to a thin layer at the interface between the two gels before these are actually separated in the resolving gel.

The Laemmli (1970) method was used for the electrophoretic separation of proteins. Thin layer polyacrylamide gels of 1.5 mm thickness were prepared by using an assembly fitted with the glass plates. The protein samples (prepared in Laemmli buffer followed by boiling at 95°C for 5 min) were separated on 12.5% SDS-PAGE gels. The gels were run in an electrophoresis chamber purchased from Hoefer Inc, USA (model name: Mighty Small II SE 250).

The gels were prepared by mixing the chemicals as listed below and were polymerized by the addition of APS and TEMED. After complete polymerization, an equal amount of protein extract (10 µg) in an equal volume of the buffer (10 µl) was loaded. A current of 30 mA was continuously supplied for an initial 15 minutes, followed by 80mA for the rest of the running period. The current supply was disconnected immediately after the tracking dye Bromophenol blue left the running buffer.

The protein samples were mixed with 0.25 x volume of 4 x sample buffer and were heated at 95°C for 5 min. After cooling, the samples were loaded onto the stacking gel. The PageRuler prestained protein ladder (MBI Fermentas, Germany) was used as a marker for the molecular weight determination.

Stacking gel (4%)

4%	Acrylamid/Bis-acrylamid (29:1)
125mM	Tris/HCl pH 6.8
0.2%	SDS
0.1%	TEMED
0.6%	APS

Resolving gel (12,5%)

12.5%	Acrylamid/Bis-acrylamid (29:1)
375mM	Tris/HCl pH 8.8

0.2%	SDS
0.05%	TEMED
0.33%	Ammonium persulfate

Running Buffer

129mM	Glycin
0.1%	SDS

3.5.4 Coomassie-Staining of Proteins

The stacking gel was removed and the running gel was soaked into the Coomassie staining solution (Sambrook and Gething, 1989) to stain the proteins separated in the polyacrylamide gel. The gel was incubated in the staining solution for 1 hour on a rocking platform at RT. The gel was washed with bidest water and again incubated with the destaining solution for 1 hour at RT. The protein bands were now clearly visible.

Coomassie – Staining solution

10%	Acetic acid
7%	Methanol
1%	Coomassie Briliant Blue R-250

Destaining solution

10%	Acetic acid
7%	Methanol

3.5.5 Western blotting**3.5.5.1 Transfer on a nitrocellulose membrane**

The proteins in a polyacrylamide gel were transferred to a nitrocellulose membrane (Protran BA 83 Cellulose nitrate, Schleicher und Schuell) using a Biorad transfer tank. The transfer was carried out at 120 V for 2 h, while maintaining 10°C temperature of the transfer bath. SDS-coated negatively charged proteins are transferred to the membrane when the voltage is applied. The protein transfer on nitrocellulose membrane was checked by staining with Ponceau S for 1 min.

The membrane was washed twice with 15 ml of wash buffer (PBS-Tween), each for 10 min with gentle shaking on a rocking platform.

3.5.5.2 Immunodetection of proteins through Chemiluminescence

The membrane was incubated overnight in blocking solution at 4°C to reduce unspecific binding. The membrane was washed in PBS-Tween buffer on a rocking platform and incubated in the primary antibody solution (diluted in blocking solution) for 1 h at RT. The membrane was washed again three times in the wash buffer for 10 min each and was incubated in the secondary antibody solution with shaking for 1 hour at RT. The membrane was washed thrice (for 10 min each) with wash buffer and then washed twice with Assay buffer. The membrane was ready for chemiluminescent detection.

The chemiluminescent detection is based on the interaction of a chemiluminescent substrate with an enzyme that has been conjugated to an antibody. As the enzyme-antibody conjugate binds to the substrate, a reaction is catalyzed resulting in light emission. In the present study, a chemiluminescent kit (Western-Star™ System, Applied Biosystems) was used for the detection of the blot according to the instructions of the kit manufacturer. The enzymatic dephosphorylation of the substrate CDP-Star® through the alkaline phosphatase conjugated to the secondary antibody emitted light signals which were captured by the gel documentation system (ChemiDoc XRS System, BioRad) equipped with a CCD camera.

3.6 Software/Tools used in the present study

3.6.1 Homology modelling

The coordinates required for drawing the homology models were provided by the online tool “SWISS-MODEL” (Arnold *et al.*, 2006, Kiefer *et al.*, 2009, Peitsch, 1995). The models were drawn in the software PYMOL version 1.4. SWISS-MODEL comparative given protein with the crystal structures available in the Protein Data Bank (PDB). It selected hAQP4 crystal structure (PDB entry # 3GD8) as template in case of TaTIP2;2 whereas it used spinach PIP2 crystal structure (PDB entry # 2B5F) as template in case of NtPIP2;1.

3.6.2 Primer designing Tools

The commercial program Vector NTI was generally used to design the primers. However, for site-directed mutagenesis, the online primer-designing tool provided by Stratagene was also used for counter-checking.

3.6.3 Sequence alignments

Sequence alignments were generated using BioEdit software version 7.0.9 (Hall, 1999) that incorporates multiple sequence alignment tools of ClustalX.

3.6.4 Verification of sequencing quality

The program Chromas Lite version 2.0 was used to open the histograms provided by the sequencing service and the sequencing quality was determined.

3.7 Synthetic Oligonucleotides

All the primers were synthesized by Eurofins MWG Operon, Germany.

4 SUMMARY

The plant aquaporin TaTIP2;2 investigated in this study is permeable to both water and ammonia. Based on previous findings that in TaTIP2;2 ammonia transport is mercury sensitive, but water transport is mercury insensitive, a detailed study was planned to get a deeper insight into the coordination site(s) for Hg. Further, this study was aimed to shed light on the mechanism of metal inhibition, and provide evidence for the function of the tetrameric pore.

The mutational analyses involve substitutions of the native Cys residues and introduction of an already known Hg-sensitive site belonging to another TIP isoform. The results reveal that the presence of a Cys at a particular site in TM3 of the plant TIPs would render them Hg-sensitive. A consensus region of metal sensitivity in plant AQPs (similar to the one in mammalian AQPs) has also been proposed for accommodating a Hg-sensitive Cys. However, in case of plants, the PIPs are well-characterized aquaporins and in this family too, no report of Hg sensitivity is available to date. The consensus region may be located at different positions in different families of plant AQPs. In case of the TIP family, it is located in TM3.

The issue of the different Hg sensitivities of water and ammonia transport function in TIP could not be resolved and still remains controversial. As the decrease in P_{NH_3} may take place because of ammonia-mercury complex formation (and not because of Cys-Hg coordination), further investigations have been suggested to solve this issue. Particular attention may be laid on acquiring some stoichiometric data that determines the decrease in ammonia concentration available to enter the pore mouth versus the decrease of ammonia inside the pore because of the mercury inhibition. The application of selective inhibitors for water transport and for the putative central pore of AQPs would also be useful, if the gases are indeed conducted through the central pore. This study doesn't provide any further evidence on the presence of a separate gas pore.

Another part of this study involved a functional approach to investigate the molecular determinants of ammonia selectivity in AQPs. The sequence alignment including predominantly water conducting AQPs in comparison to the ammonia conducting ones suggested a couple of amino acids which were distinguishable between the two AQP categories. The residues identified in NtPIP2 are Val, Val and Ala positioned at 117, 197 and 256 respectively. The corresponding residues in case of TaTIP2;2 are Ile, Leu and Gly.

The failure in inducing ammonia conductance in PIP2 and no effect of the mutations on TIP in turning it into a water channel indicate their insignificant role in ammonia permeability in AQPs. However, a drastic effect on water permeability in PIP2 (and

not in TIP) suggests their role in the water transport function of the protein. It is tempting to speculate that the above-mentioned residues are part of the mechanism facilitating the water conductance in AQPs, either by direct interaction with the water molecules or by physical effects on the pore. The varying effects of the given residues may be attributed to the difference in structure between TIPs and PIPs besides pointing towards the presence of a central pore in AQPs.

Although the protein abundance in various mutants could not be determined because of the lack of an appropriate antibody, the isosteric similarities among the substituted residues lead to consider it as less likely. This study also suggests another position among the AQPs which is rather more conserved and should be considered in future work.

A remarkable part of the present work encompasses the generation of a number of protein chimeras and the mutations in the essential pore structures of AQPs. It was attempted to completely swap the ar/R region between TaTIP2;2 and NtPIP2;1. Furthermore, Asn of both the NPA motifs were also mutated to His. Surprisingly, in case of the former mutations, none of those were permeable to either water or ammonia. The latter mutants were also nonfunctional, however, proton leakage was observed which indicated that the mutations didn't hinder the protein expression.

Some domains of structural and functional importance were also swapped between TIP and PIP. These included exchange of loops A, D; the transmembrane helices 2, 5 and the C-terminus. None of the chimeric proteins showed any ammonia/water transport function. Unfortunately, in case of the TIP chimeras, the protein expression couldn't be determined because of the lack of an appropriate antibody. Also, in case of TIP, there is readily no interpretation available for the loss of ammonia/water transport function after swapping its loop A and TM2 with those of PIP2.

Zusammenfassung

In dieser Arbeit wurde das Aquaporin TaTIP2;2 untersucht, welches eine Permeabilität sowohl für Wasser als für Ammoniak zeigte. Basierend auf vorherigen Erkenntnissen, dass in TIP2.2 Ammoniaktransport, aber nicht Wassertransport durch Quecksilber inhibiert werden kann, war eine detaillierte Studie geplant, um einen tieferen Einblick in die Angriffstelle(n) für Hg zu bekommen. Des Weiteren war das Ziel, den Mechanismus der Quecksilberinhibition näher zu beleuchten und Evidenz für die Funktion der zentralen Pore im Tetramer zu finden.

Mutationsanalysen beinhalten den Austausch von Aminosäuren der natürlich vorhandenen Cysteinreste, sowie das Einbringen eines Quecksilber sensitiven Abschnitts welcher zu einer anderen TIP Isoform gehört. Die Ergebnisse offenbaren, dass die Anwesenheit von Cystein an einer bestimmten Stelle in TM3 der pflanzlichen TIP Isoformen diese Hg sensitiv machen. Es wurde vorgeschlagen, dass eine metallsensitive Konsensus Region in pflanzlichen Aquaporinen (ähnlich zu den AQPs in Säugetieren) ein Hg-sensitives Cystein enthält. Allerdings wurde in pflanzlichen PIPs, die zu einer sehr gut charakterisierten Familie von Aquaporinen gehören, bisher nicht über Hg-Sensitivität berichtet. Die Konsensus Region könnte an verschiedenen Positionen in den unterschiedlichen Familien der pflanzlichen Aquaporine lokalisiert sein. Im Fall der TIP Familie ist es in TM3 lokalisiert.

Das Problem der unterschiedlichen Quecksilber-Empfindlichkeit der Wasser- bzw. Ammoniak-Leitfähigkeit von TIP konnte nicht gelöst werden und ist nach wie vor kontrovers. Die Abnahme von P_{NH_3} könnte durchaus aufgrund einer Komplexbildung zwischen Ammoniak und Quecksilber zu Stande kommen (und nicht aufgrund einer Cys-Hg Wechselwirkung). Um dieses Problem zu lösen wurden weiterführende Experimente vorgeschlagen. Dabei könnte ein besonderes Augenmerk darauf liegen, stöchiometrische Daten bezüglich der Ammoniak-Verfügbarkeit und dessen Abnahme am Poren-Eingang im Vergleich zur Abnahme innerhalb der Pore aufgrund der Quecksilber-Inhibition zu erhalten. Indem man selektive Inhibitoren für die Wasser- sowie die putative Tetramer-Pore des Aquaporins verwendet, könnten ebenfalls hilfreiche Untersuchungen durchgeführt werden, gesetzt den Fall, dass das Gas tatsächlich durch die zentrale Pore tritt. Die vorliegende Arbeit bietet keinen weiteren Beleg für die Existenz einer separaten Gas-Pore.

Ein weiterer Teil der vorliegenden Arbeit schloss die Untersuchung der molekularen Grundlagen der Ammoniak-Selektivität von Aquaporinen mit Hilfe eines funktionellen Ansatzes mit ein. Die Sequenz-Vergleiche von hauptsächlich wasserleitfähigen im Gegensatz zu Ammoniak-leitfähigen Aquaporinen ergaben, dass sich einige Aminosäuren innerhalb der jeweiligen Aquaporin-Gruppe unterschieden. Bei den identifizierten

Aminosäuren in NtPIP2 handelt es sich um Val, Val und Ala an den Positionen 117, 197 und 256. Die entsprechenden Aminosäuren im Fall von TaTIP2;2 sind Ile, Leu und Gly.

Der Umstand, dass Ammoniak-Leitfähigkeit in PIP2 nicht induziert, bzw. in TIP nicht unterbunden werden konnte, zeigt, dass PIP2 Aquaporine prinzipiell für Ammoniak-Transport nicht von Bedeutung sind. Allerdings unterstreicht der drastische Effekt auf die Wasserpermeabilität im Falle von PIP2, nicht jedoch bei TIP, deren Bedeutung für den Wassertransport. Daher liegt es nahe anzunehmen, dass die oben angesprochenen Aminosäure-Positionen ein Teil des Wassertransport-Mechanismus in Aquaporinen sind, entweder durch direkte Interaktion mit den Wasser-Molekülen, oder durch physikalischer Effekte im Porenbereich. Die unterschiedlichen Effekte bestimmter Aminosäurepositionen können sich außer aus der Anwesenheit einer zentralen Pore noch aus weiteren strukturellen Unterschieden zwischen TIP und PIP Aquaporinen ergeben.

Obwohl für zahlreiche Mutanten aufgrund des Fehlens geeigneter Antikörper die Menge exprimierten Proteins nicht bestimmt werden konnte, erscheint diese Möglichkeit aufgrund der isosterischen Ähnlichkeiten unter den ausgetauschten Aminosäure jedoch weniger wahrscheinlich. Die vorliegende Studie weist auf eine weitere Aminosäure-Position hin, die höher konserviert ist und in zukünftigen Studien betrachtet werden sollte.

Ein großer Teil dieser Arbeit beschäftigt sich mit der Herstellung verschiedener Protein chimären und Mutationen in essentiellen Porenstrukturen von AQPs. Ziel war es, die komplette ar/R-region zwischen TaTIP2;2 und NtPIP2;1 auszutauschen. Es wurden auch die Asn beider NPA Motive zu His mutiert. Erstere waren erstaunlicherweise weder für Wasser noch für Ammoniak permeabel. In Letzteren konnten Protonen Leckströme beobachtet werden, ein Hinweis darauf, dass die Mutationen die Proteinexpression nicht unterdrückten.

Manche für Aufbau und Funktion wichtigen Domänen wurden ebenfalls zwischen TIP und PIP ausgetauscht. Dies umfasste den Austausch der Loops A, D; die Transmembranhelices 2 und 5 sowie den C-Terminus. Keine dieser Protein chimären zeigte eine Funktion bezüglich Wasser- oder Ammoniakleitfähigkeit. Leider konnte im Falle der TIP-Chimären keine Expression des Proteins nachgewiesen werden, da ein passender Antikörper fehlte. Auch im Falle von TIP kann momentan keine Deutung für den Funktionsverlust bezüglich Ammoniak/Wasser vorgenommen werden, nachdem der Loop A und TM2 mit denen von PIP2 ausgetauscht wurde.

Appendix 2

Logoplots of the amino acid residues around the ar/R constriction in AQPs.

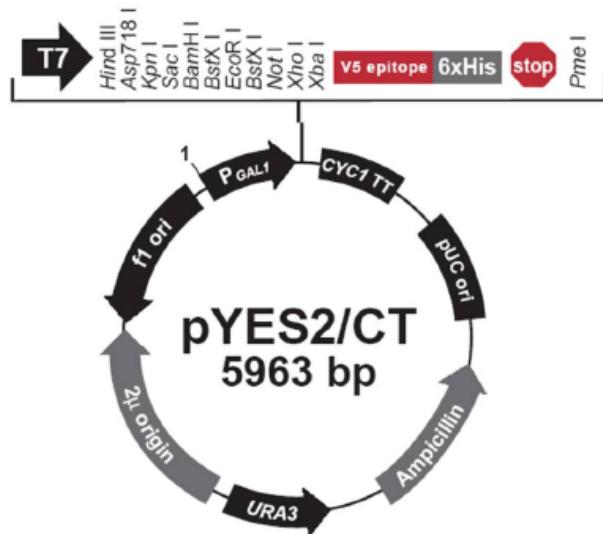

Figure: Logoplots of the amino acid residues around the aromatic/Arg restriction regions. The water permeable AQP1 has been aligned against the ammonia-permeable aquaporins AQP3, 7, 8, 9, and 10. The numbers belong to the constituents of the SF tetrad and represent corresponding positions in AQP1. The left panel includes the H2 position of the SF region. The right panel also includes the so-called “consensus region of metal sensitivity” which is located N-terminus to the second NPA motif and has been often referred to in the present study. The position H5 has His residue in ammonia- and glycerol-permeable AQPs. This position is usually replaced by a Gly in the case of the ammonia- and water permeable AQP8, an Ile. The variations in molecular signatures apart from the SF region have been highlighted by arrows. In case of aqua-ammoniaporins, the position 184 would always contain a Gly and the position 190 either an Ala or a Cys residue. (Adopted from Litman *et al.*, 2009).

Appendix 4

List of Abbreviations

xg	x gravity
AQP	Aquaporin
dNTP	deoxy-Nukleosidtidtriphosphat
EDTA	Ethyldiamintetraacetat
hAQP1	human Aquaporin 1
NtPIP2;1	<i>Nicotiana tabacum</i> plasma membrane intrinsic protein 2;1
PAGE	Polyacrylamide gel electrophoresis
PCMBS	<i>p</i> -chloromercuribenzene sulfonate
PCR	Polymerase chain reaction
P_f	Osmotic permeability coefficient
P_{NH_3}	Ammonia permeability coefficient
rpm	revolutions per minute
SDS	Sodium Dodecylsulfate
TaTIP2;2	<i>Triticum aestivum</i> tonoplast intrinsic protein 2;1
Taq	<i>Thermophilus aquaticus</i>
TEMED	(N, N, N', N'-tetramethylethylenediamine)
U	Unit

Appendix 5

Single and triple genetic codes of amino acids

A	Ala	Alanin
C	Cys	Cystein
D	Asp	Asparaginsäure
E	Glu	Glutaminsäure
F	Phe	Phenylalanin
G	Gly	Glycin
H	His	Histidin
I	Ile	Isoleucin
K	Lys	Lysin
L	Leu	Leucin
M	Met	Methionin
N	Asn	Asparagin
P	Pro	Prolin
Q	Gln	Glutamin
R	Arg	Arginin
S	Ser	Serin
T	Thr	Threonin
V	Val	Valin
W	Trp	Tryptophan
Y	Tyr	Tyrosin

Curriculum Vitae

Name: Muhammad Ayaz
Date of Birth: January 1, 1973
Place of Birth: Multan (Pakistan)
Marital status: Single
Nationality: Pakistani

Academic Achievements:

1982	Primary-level certificate	(Pakistan)
1987	Secondary-level certificate	(Pakistan)
1990	Higher-Sec-level certificate	(Pakistan)
1996	BSc (Hons) in Agriculture	Univ of Arid Agriculture Rawalpindi, (Pakistan)
1999	MPhil in Botany	Department of Biological Sciences, Quaid-e-Azam Univ; Islamabad (Pak) (Advisor: Dr M. Fayyaz Chaudhary)
1999- 2002	Research assistant (volunteer)	Plant Tissue Culture/Transformation Lab, National Agri Res Center, Islamabad/ Quaid-e-Azam Univ; Islamabad (Pak)
2003-2006	No academic achievements	
2006-2011	PhD candidate	Tech. Univ. Darmstadt, Germany (Advisor: Prof Dr Ralf Kaldenhoff)
	2006-2008 (Full-time)	
	2008-2011 (Part-time)	

Ehrenwörtliche Erklärung:

Ich erkläre hiermit ehrenwörtlich, dass ich die vorliegende Arbeit selbständig angefertigt habe. Sämtliche aus fremden Quellen direkt oder indirekt übernommene Gedanken sind als solche kenntlich gemacht. Die Arbeit wurde bisher keiner anderen Prüfungsbehörde vorgelegt und noch nicht veröffentlicht.

Muhammad Ayaz
